4. Assessment of the yellowfin sole stock in the Bering Sea and Aleutian Islands

Thomas K. Wilderbuer, Daniel G. Nichol and James Ianelli

Executive Summary

Summary of Changes in Assessment Inputs

Changes to the input data

1) 2014 fishery age composition.
2) 2014 survey age composition.
3) 2015 trawl survey biomass point estimate and standard error.
4) Estimate of the discarded and retained portions of the 2014 catch.
5) Estimate of total catch made through the end of 2015. Catch of 150,000 t assumed for 2016 and 2017 projection.

Changes to the assessment methodology

Changes were made to the weight-at-age empirical data where values from ages 11 to 20 were smoothed. The assessment updates last year's with results and management quantities that are moderately lower than the 2014 assessment. Yellowfin sole continue to be well-above B_{MSY} and the annual harvest remains below the ABC level. The female spawning stock is in a slow downward trend.

Summary of Results

Quantity	As estimated or *specified last* year for: 2015	2016	As estimated or *recommended this* year for: 2016	2017
M (natural mortality rate)	0.12	0.12	0.12	0.12
Tier	1a	1a	1a	1a
Projected total (age 6+) biomass (t)	2,127,800	2,100,000	2,170,000	2,086,200
Female spawning biomass (t)				
Projected	644,200	648,600	702,200	696,200
B_0	989,800		1,107,000	
B_{MSY}	391,000		435,000	
F_{OFL}	0.125	0.125	0.105	0.105
$maxF_{ABC}$	0.117	0.117	0.098	0.098
F_{ABC}	0.117	0.117	0.098	0.098
OFL (t)	266,400	262,900	228,100	219,200
maxABC (t)	248,800	245,500	211,700	203,500
ABC (t)	248,800	245,500	211,700	203,500
Status	As determined *last* year for: 2013	2014	As determined *this* year for: 2014	2015
Overfishing	No	n/a	No	n/a
Overfished	n/a	No	n/a	No
Approaching overfished	n/a	No	n/a	No

Projections are based on estimated catches of 150,000 t used in place of maximum ABC for 2016 and 2017.

Responses to SSC and Plan Team Comments on Assessments in General

General comments for all assessments:

The SSC requests that stock assessment authors utilize the following model naming conventions in SAFE chapters:

Model 0: last years' model with no new data,
Model 1: last years' model with updated data, and
Model numbers higher than 1 are for proposed new models.
The authors plan to use the proposed model numbers in future assessments.

Responses to SSC and Plan Team Comments Specific to this Assessment

The SSC appreciates the author's responsiveness to the request to update the assessment with new maturity data. The SSC supports the Plan Team recommendation to test for differences of 1992/1993 and 2012 maturity curves, and to pool all maturity data for the next assessment if there are no significant differences. The SSC also supports Plan Team recommendations with respect to the weight-at-age analysis for the next assessment. The SSC looks forward to the analysis of the retrospective plots and associated bias in 2015.

Plan Team comments

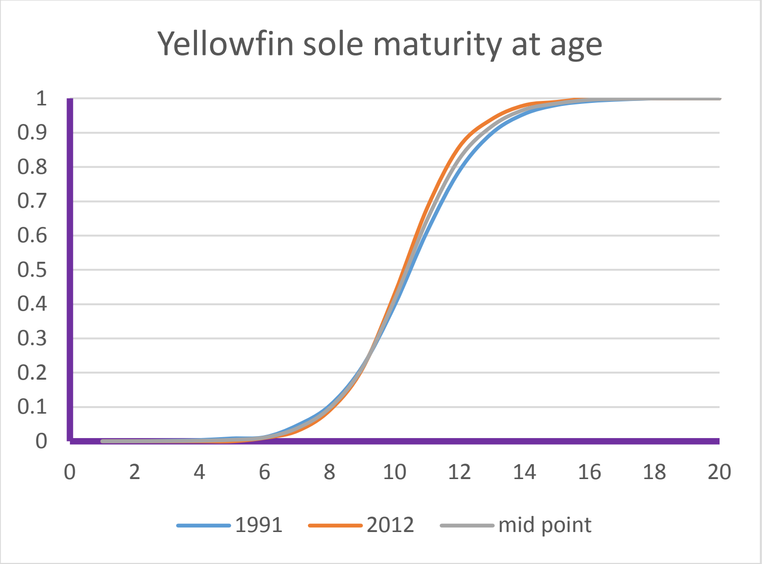
There was some discussion about the new maturity schedule and its seeming lack of significant difference from the previously used maturity data; the new maturity data increased the FSB by 2%.
The Team recommends testing for differences of maturity curves, and if no significant differences are found pooling all maturity data for next assessment.
In 2011, the authors examined four models of weight at age for yellowfin sole (the below model numbers refer to the 2011 assessment models, not the current year):

Model 0: parametric fit of time-invariant and age-specific growth increments to the year-and-age-specific survey data
Model 1: year-and-age-specific mean weights from the survey
Model 2: growth increments from Model 0 multiplied by random year-and-age effects
Model 3: growth increments from Model 0 multiplied by random year-and-age effects and temperature-dependent year effects

The Team recommends that the 2011 weight-at-age analysis be revisited with the following modifications:
1. Model 1 in the 2011 analysis was regarded as the "truth," meaning that it was determined to be the preferred model a priori. Because the weights at age in Model 1 were empirical estimates obtained from the survey, the Team feels that they necessarily contain some amount of sampling error, and so should not be viewed as perfect estimates.

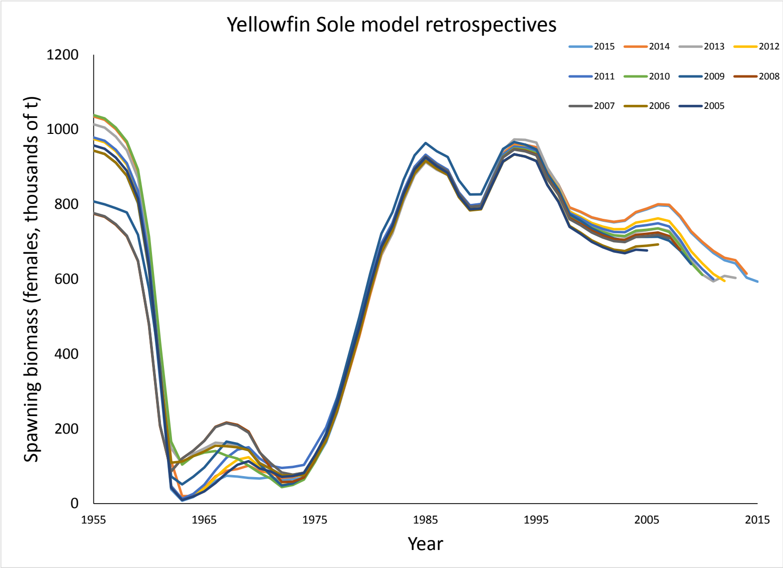
2. Models 2 and 3 contain more nominal parameters than data, and are unnecessarily conditioned on the results from Model 0. The Team feels that one or more models with fewer parameters should also be *considered (e.g., some sort of random effects model or other smoother, where the growth increments are not tied to the results of Model 0).*

For the response on maturity, visual inspection of the maturity-at-age curves from the two collection periods (1991-1992 and 2012) indicate nearly identical estimates (shown below), therefore testing for statistical significance was not performed. Mid-points of the maturity-at-age estimates from the two curves were used in the assessment.



For the issues related to weight-at-age, the empirical weight-at-age data from annual shelf survey sampling (Model 1) are not considered perfect but rather reliable empirical estimates to be used in stock assessment modeling. In response to these comments, we closely re-examined the growth model code and the model description and equations in the text. One coding error was found and fixed and we also noticed an age subscript (j) for Model 2 in the text that needed to be omitted. This extra subscript in the Model 2 equation would allow for more parameters being estimated than data, which was not the intent. Also corrected the text to describe Epsilon as an error term for year-effect only (and not age-effect). Thus Model 2 can now correctly be described as the growth increments from Model 0 multiplied by random year effects, and Model 3 as the growth increments from Model 0 multiplied by random year and temperature dependent year effects.

Model performance was examined by considering the fit of Models 2 and 3 to the empirical data instead of comparing female spawning biomass trajectories (shown for Models 2 and 3 in Fig. 4.15).



In response to including a retrospective plot and analysis the figure above was developed. The value of Mohn's statistic for these years is -0.092. Some of the years exhibit a successive pattern where FSB appears to be higher than what was previously estimated. The last two years (2014 and 2015) are nearly identical.

Introduction

The yellowfin sole (*Limanda aspera*) is one of the most abundant flatfish species in the eastern Bering Sea (EBS) and currently is the target of the largest flatfish fishery in the world. They inhabit the EBS shelf and are considered one stock. Abundance in the Aleutian Islands region is negligible.

Yellowfin sole are distributed in North American waters from off British Columbia, Canada, (approx. lat. 49° N) to the Chukchi Sea (about lat. 70° N) and south along the Asian coast to about lat. 35° N off the South Korean coast in the Sea of Japan. Adults exhibit a benthic lifestyle and occupy separate winter, spawning and summertime feeding distributions on the eastern Bering Sea shelf. From over-winter grounds near the shelf margins, adults begin a migration onto the inner shelf in April or early May each year for spawning and feeding. The directed fishery has typically occurred from winter through autumn (Wilderbuer et al. 1992). Yellowfin sole are managed as a single stock in the BSAI management area as there is presently no evidence of stock structure.

Fishery

Yellowfin sole have annually been caught with bottom trawls on the Bering Sea shelf since the fishery began in 1954 and were overexploited by foreign fisheries in 1959-62 when catches averaged 404,000 t annually (Fig. 4.1, top panel). As a result of reduced stock abundance, catches declined to an annual average of 117,800 t from 1963-71 and further declined to an annual average of 50,700 t from 1972-77. The lower yield in this latter period was partially due to the discontinuation of the U.S.S.R. fishery. In the early 1980s, after the stock condition had improved, catches again increased reaching a peak of over 227,000 t in 1985.

During the 1980s, there was also a major transition in the characteristics of the fishery. Yellowfin sole were traditionally taken exclusively by foreign fisheries and these fisheries continued to dominate through 1984. However, U.S. fisheries developed rapidly during the 1980s in the form of joint ventures, and during the last half of the decade began to dominate and then take all of the catch as the foreign fisheries were phased out of the EBS. Since 1990, only domestic harvesting and processing has occurred.

The management of the yellowfin sole fishery changed significantly in 2008 with the implementation of Amendment 80 to the BSAI Fisheries Management Plan. The Amendment directly allocated fishery resources among BSAI trawl harvesters in consideration of their historic harvest patterns and future harvest needs in order to improve retention and utilization of fishery resources by the non-AFA trawl catcher/processor fleet. This was accomplished by extending the groundfish retention standards to all H&G vessels and also by providing the ability to form cooperatives within the newly formed Amendment 80 sector. In addition, Amendment 80 also mandated additional monitoring requirements which included observer coverage on all hauls, motion-compensating scales for weighing samples, flow scales to obtain accurate catch weight estimates for the entire catch, no mixing of hauls and no on-deck sorting. The partitioning of TAC and PSC (prohibited species catch) among cooperatives has significantly changed the way the annual catch has accumulated (Fig 4.1, bottom panel) and the rate of target catch per bycatch ton. There is now a more even and slow attainment of the annual catch relative to the pre-Amendment 80 fishing behavior.

Yellowfin sole are usually headed and gutted, frozen at sea, and then shipped to Asian countries for further processing (see “market profile” in the 2011 economic SAFE report for details). In 2010, following a comprehensive assessment process, the yellowfin sole fishery was certified under the Marine Stewardship Council environmental standard for sustainable and well-managed fisheries. The certification also applies to all the major flatfish fisheries in the BSAI and GOA. The total annual catch (t) since implementation of the MFCMA in 1977 is shown in Table 4.1.

Also in 2010, federally permitted vessels using non-pelagic trawl gear whose harvest results in flatfish retained catch that is greater than any other retained fishery category were required to use modified trawl gear. The modifications required the use of elevating devices to raise the section of the trawl warps between the doors and the trawl wing tips by 2.5 inches off the seafloor. The purpose of the management action was to reduce damage of non-target animals, particularly those that form habitat structure or support other fisheries while not substantially reducing flatfish catch rates or causing gear handling problems (Rose et al. 2010).

The 1997 catch of 181,389 t was the largest since the fishery became completely domestic but was at lower levels from 1998 – 2010, averaging 94,004 t. The catch has increased the past four years (2010-2014) averaging 152,000 t. The 2013 catch totaled 165,000 t (73% of the ABC), the highest annual catch in the past 17 years. For 2015, the catch distribution has been spread out fairly evenly from January through May and also August and September with the majority coming from 4 BSAI management areas (509, 513, 514, 521). As of mid-October 2015, the fishing season is ongoing. In order to estimate the total 2015 catch for the stock assessment model, the average proportion of the 2010-2014 cumulative catch attained by the 38th week of the year (mid-September) was applied to the 2015 catch amount at the same time period and results in a 2015 catch estimate of 122,000 t (49% of the ABC). The size composition of the 2015 catch for both males and females, from observer sampling, are shown in Figure 4.2, the catch proportions by month and area are shown in Figure 4.3, and maps of the locations where yellowfin sole were caught in 2014, by month, are shown in Figure 4.4. The average age of yellowfin sole in the 2014 catch is estimated at 12.5 and 12.3 years for females and males, respectively.

The time-series of catch in Table 6.1 also includes yellowfin sole that were discarded in domestic fisheries during the period 1987 to the present. Annual discard estimates were calculated from at-sea sampling (Table 4.2). The rate of discard has ranged from a low of 2% of the total catch in 2012 to 30% in 1992. The trend has been toward fuller retention of the catch in recent years, and with the advent of the Amendment 80 harvest practices, discarding is at its lowest level since these estimates have become available. Historically, discarding primarily occurred in the yellowfin sole directed fishery, with lesser amounts in the Pacific cod, Pollock, rock sole, flathead sole, and “other flatfish” fisheries (Table 4.3).

Data

The data used in this assessment include estimates of total catch, bottom trawl survey biomass estimates and their attendant 95% confidence intervals, catch-at-age from the fishery and population age composition estimates from the bottom trawl survey. Weight-at-age and proportion mature-at-age are also available from studies conducted during the bottom trawl surveys.

Data source	**years**
Fishery catch	1954-2015
Fishery age composition	1964-2014
Survey biomass and standard error, bottom temperature	1982-2015
Survey age composition	1979-2014
Annual length-at-age and weight-at-age	1979-2014
Maturity at age	Combined 1992 and 2012 samples

Fishery Catch and Catch-at-Age

This assessment uses fishery catch data from 1955- 2014 (shown for 1964-2014 in Table 4.1), including an estimate of the 2015 catch, and fishery catch-at-age (proportions) from 1964-2014 (Table 4.4, 1975-2014). The 2014 fishery age composition is primarily composed of fish older than 9 years with a large amount of 20+ fish.

Survey Biomass Estimates and Population Age Composition Estimates

Indices of relative abundance available from AFSC surveys have also shown a major increase in the abundance of yellowfin sole during the late 1970s, increasing from 21 kg/ha in 1975 to 51 kg/ha in 1981 (Fig. 4.2 in Bakkala and Wilderbuer 1990). These increases have also been documented through Japanese commercial pair trawl data and catch-at-age modeling in past assessments (Bakkala and Wilderbuer 1990).

Since 1981, the survey CPUEs have fluctuated widely (Fig. 4.5). Biomass estimates for yellowfin sole from the annual bottom trawl survey on the eastern Bering Sea shelf are shown in Table 4.5. The data show a doubling of survey biomass between 1975 and 1979 with a further increase to over 3.3 million t in 1981. Total survey abundance estimates fluctuated erratically from 1983 to 1990 with biomass ranging from as high as 3.5 million t in 1983 to as low as 1.9 million t in 1986. Biomass estimates since 1990 indicate an even trend at high levels of abundance for yellowfin sole, with the exception of the results from the 1999 and 2000 summer surveys, which were at lower levels. Surveys from 2001-2005 estimated an increase each year but the estimates since 2006 indicate a stable level with some annual variability. However, the 2012 estimate is a 19% decrease from 2011 and the 2013 and 2014 surveys have estimated a 17% increase over 2012. Similarly there was a 24% decrease from 2014-2015. Fluctuations of the magnitude shown between 1980 and 1990 and again between 1998 and 1999, 2008 and 2009 and also 2011 – 2012 and 2014-2015 are unreasonable considering the combined elements of slow growth and long life span of yellowfin sole combined with low to moderate exploitation rate, characteristics which should produce more gradual changes in abundance.

Variability of yellowfin sole survey abundance estimates (Fig. 4.6) is in part due to the availability of yellowfin sole to the survey area (Nichol, 1998). Yellowfin sole are known to undergo annual migrations from wintering areas off the shelf-slope break to near shore waters where they spawn throughout the spring and summer months (Nichol, 1995; Wakabayashi, 1989; Wilderbuer et al., 1992). Exploratory survey sampling in coastal waters of the eastern Bering Sea during early summer indicate that yellowfin sole concentrations can be greater in these shallower areas not covered by the standard AFSC survey than in the survey proper. Commercial bottom trawlers have commonly found high concentrations of yellowfin sole in areas such as near Togiak Bay (Low and Narita, 1990) and in more recent years from Kuskokwim Bay to just south of Nunivak Island. The coastline areas are sufficiently large enough to offer a substantial refuge for yellowfin sole from the current survey.

Over the past 15 years survey biomass estimates for yellowfin sole have shown a positive correlation with shelf bottom temperatures (Nichol, 1998); estimates have generally been lower during cold years. The 1999 survey, which was conducted in exceptionally cold waters, indicated a decline in biomass that was unrealistic. The bottom temperatures during the 2000 survey were much warmer than in 1999, and the biomass increased, but still did not approach estimates from earlier years. Average bottom temperature and biomass both increased again during the period 2001 – 2003, with the 2003 value the highest temperature and biomass observed over the 22 year time series. Given that both 1999 and 2000 surveys were conducted two weeks earlier than previous surveys, it is possible that the time difference may also have also affected the availability of yellowfin sole to the survey. If, for example, the timing of peak yellowfin sole spawning in nearshore waters corresponded to the time of the survey, a greater proportion of the population would be unavailable to the standard survey area. This trend was observed again in 2009 and 2012 when the temperatures and the bottom trawl survey point estimates were lower. Summer shelf bottom temperatures in 2012 were the 2nd coldest recorded by the survey and the time-series and resulted in a 19% decline from 2011.

We propose two possible reasons why survey biomass estimates are lower during years when bottom temperatures are low. First, catchability may be lower because yellowfin sole may be less active when cold. Less active fish may be less susceptible to herding, and escapement under the footrope of survey gear may increase if fish are less active. Secondly, bottom temperatures may influence the timing of the inshore spawning migrations of yellowfin sole and therefore affect their availability to the survey area. Because yellowfin sole spawning grounds include nearshore areas outside the survey area, availability of fish within the survey area can vary with the timing of this migration and the timing of the survey. In the case of 2012, a very cold year in the Bering Sea, it is unclear from examining survey station catches along the survey border near Kuskowkim bay if a significant portion of the biomass lies outside this border (Fig 4.7).

Yellowfin sole population numbers-at-age estimated from the annual bottom trawl surveys are shown in Table 4.6 and their occurrence in trawl survey hauls and associated collections of lengths and age structures since 1982 are shown in Table 4.7. Their total tonnage caught in the resource assessment surveys since 1982 are listed in Table 4.8 and also in an appendix table with IPHC survey catches.

Length and Weight-at-Age

Past assessments of yellowfin sole have used sex-specific, time-invariant growth based on the average length-at-age and weight-at-length relationships from the time-series of survey observations summed over all years since 1982. These weight-at-age estimates were estimated from the following relationships:

Parameters of the von Bertalanffy growth curve have been estimated for yellowfin sole, by sex, from the trawl survey database as follows:

	L_{inf}	K	t_0	n
Males	33.7	0.161	-0.111	656
Females	37.8	0.137	0.112	709

A sex-specific length-weight relationship was also calculated from the survey database using the usual power function, weight (g) = a Length(cm)^b, where a and b are parameters estimated to provide the best fit to the data (Fig. 4.8).

	a	b	n
males	0.00854	3.081	2,701

females	0.0054	3.227	3,662

These estimates of weight at length were applied to the annual trawl survey estimates of population length at age averaged over all years, by sex, to calculate the weight at each age (Fig. 4.8). Since the resulting estimates of weight-at-age were highly variable for fish older than 11 years, ages 11-20 were smoothed using a five year average smoothing method for 1982-2015.

Recent applications of dendrochronology (tree-ring techniques) have been used to develop biochronologies from the otolith growth increments of northern rock sole (*Lepidopsetta polyxystra*), yellowfin sole and Alaska plaice (*Pleuronectes quadrituberculatus*) in the eastern Bering Sea. These techniques ensure that all growth increments are assigned the correct calendar year, allowing for estimation of somatic growth by age and year for chronologies that span approximately 25 years (Matta et al. 2010). The analysis indicated that yellowfin sole somatic growth has annual variability and is positively correlated with May bottom water temperature in the Bering Sea (Fig. 4.9).

The relationship between temperature and growth was further explored by reanalyzing yellowfin sole growth by age and year. Length-weight data collected when obtaining otolith (age) samples in RACE surveys (n=7,000 from 1987, 1994 and 1999-2009) also indicate that weight at age exhibits annual variability and is highly correlated with summer bottom water temperature observations with a lag of 2-3 years for the temperature effect to be seen (shown for age 5 fish in figure 4.10) . These observations were then extended back to 1979 using survey population length-at-age estimates (since weight-at-age is a power function of the length-at-age, Clark et al. 1999, Walters and Wilderbuer 2000).

In this assessment the reanalyzed growth data were incorporated and growth was modeled as time-varying and temperature-dependent functions input into an age-structured stock assessment model and then comparing the results with the base model that uses time-invariant growth. Four growth models were developed as follows: Mean age-specific somatic body mass (here referred to as weight-at-age) is modeled as a von Bertalanfy growth function in the initial year of the stock assessment (1954) and projected forward such that the model expected mean weight at age *j* in year *i* for a given sex is constant over the projection (Model 0). In Model 1 the annual observed population mean weight-at-age (time-varying) is used in the stock assessment model. Model 2 is a fit to the data used in Model 1 by the estimation of random year specific parameters and Model 3 estimates annual weight-at-age as a function of annual May sea surface temperature anomalies. The growth models are as follows:

Models

Model			
0	$\hat{w}_{ij} = \hat{w}_{i-1,j-1} + g_j$	$i > 1954,\ j > 1$	Constant fixed growth
1	$\hat{w}_{ij} = w_{ij},$ $\hat{w}_{ij} = \overline{w}_{\square j}$	$1982 \le i \le 2014,$ $i < 1982,\ i > 2014$	As estimated for each age from survey data
2	$\hat{w}_{ij} = \hat{w}_{i-1,j-1} + g_j e^{\varepsilon_i}$	$i > 1954,\ j > 1 \quad \varepsilon_i \sim N\left(0, \sigma_g^2\right)$	Year-effect freely estimated on growth increment
3	$\hat{w}_{ij} = \hat{w}_{i-1,j-1} + g_j e^{\varepsilon_i}$ $\varepsilon_i = T_i \alpha + \delta_i$	$i > 1954,\ j > 1$ $\delta_i \sim N\left(0, \sigma_{residual}^2\right)$	Year-effect on growth increment linked to temperature conditions

where w_{ij} represents the observed estimates of mean weights at age and year, g_j is the expected age-specific growth increment in the most recent completed year (as estimated from the a sex-specific von-Bertalanfy growth curve) and ε_i is a process error term which is modeled as to have a random year-effect in model 2. In model 3 temperature anomalies are introduced for the entire period and the parameter α scales them and the residual variance, $\sigma^2_{residual}$, is estimated internally.

For Models 2 and 3, the negative log-likelihood function for the weight-at-age data applied was:

$$-\ln L_w = \sum_{i=1982}^{2014} \sum_{j=5}^{15} \frac{n_{ij}\left(\ln w_{ij} - \ln \hat{w}_{ij}\right)^2}{2\sigma^2_{residual}}$$

Maturity-at-age

Maturity information collected from yellowfin sole females during the 1992 and 1993 eastern Bering Sea trawl surveys have been used in this assessment for the past 20 years (Table 4.10). Nichol (1995) estimated the age of 50% maturity at 10.5 years based on the histological examination of 639 ovaries. Maturity has recently been re-evaluated from a histological analysis of ovaries collected in 2012 (Table 4.10). Results were very similar to the earlier study with only a 2% difference in estimates of yellowfin sole female spawning biomass (TenBrink and Wilderbuer, In press). In addition, the SSC requested that the assessment use a maturity schedule that uses estimates derived from both the 1992 and the 2012 collections (Table 4.10). For yellowfin sole sexual maturity occurs well after the age of entry into the fishery. Yellowfin sole females are 82% selected to the fishery by age 10 whereas they have been found to be only 40% mature at this age.

Analytic Approach

Model Structure

The abundance, mortality, recruitment and selectivity of yellowfin sole were assessed with a stock assessment model using the AD Model Builder language (Fournier et al. 2012; Ianelli and Fournier 1998). The conceptual model is a separable catch-age analysis that uses survey estimates of biomass and age composition as auxiliary information (Fournier and Archibald 1982). The assessment model simulates the dynamics of the population and compares the expected values of the population characteristics to the characteristics observed from surveys and fishery sampling programs. This is accomplished by the simultaneous estimation of the parameters in the model using the maximum likelihood estimation procedure. The fit of the simulated values to the observable characteristics is optimized by maximizing a log(likelihood) function given some distributional assumptions about the observed data.

The model starts at age one and fish older than twenty are allowed to accumulate into a plus group. Since the sex-specific weight-at-age for yellowfin sole diverges after age of maturity (about age 10 for 40% of the stock) with females growing larger than males, the current assessment model is coded to accommodate the sex-specific aspects of the population dynamics of yellowfin sole. The model allows for the input of sex-specific estimates of fishery and survey age composition and weight-at-age and provides sex-specific estimates of population numbers, fishing mortality, selectivity, fishery and survey age composition and allows for the estimation of sex-specific natural mortality and catchability. The model retains the utility to fit combined sex data inputs.

The suite of parameters estimated by the model are classified by three likelihood components:

Data component	Distributional assumption
Trawl fishery catch-at-age	Multinomial
Trawl survey population age composition	Multinomial
Trawl survey biomass estimates and S.E.	Log normal

The total log likelihood is the sum of the likelihoods for each data component (Table 4.11). The likelihood components may be weighted by an emphasis factor, however, equal emphasis was placed on fitting each likelihood component in the yellowfin sole assessment except for the catch. The AD Model Builder software fits the data components using automatic differentiation (Griewank and Corliss 1991) software developed as a set of libraries (AUTODIFF C++ library). Table 4.11 also presents the key equations used to model the yellowfin sole population dynamics in the Bering Sea and Table 4.12 provides a description of the variables used in Table 4.11.

Sharp increases in trawl survey abundance estimates for most species of Bering Sea flatfish between 1981 and 1982 indicate that the 83-112 trawl was more efficient for capturing these species than the 400-mesh eastern trawl used in 1975, and 1979-81. Allowing the model to tune to these early survey estimates would most likely underestimate the true pre-1982 biomass, thus exaggerating the degree to which biomass increased during that period. Although this underestimate would have little effect on the estimate of current yellowfin sole biomass, it would affect the spawner and recruitment estimates for the time-series. Hence, the pre-1982 survey biomass estimates were omitted from the analysis.

The model of yellowfin sole population dynamics was evaluated with respect to the observations of the time-series of survey and fishery age compositions and the survey biomass trend since 1982.

Parameters Estimated Outside the Assessment Model

Natural mortality (M) was initially estimated by a least squares analysis where catch-at-age data were fitted to Japanese pair trawl effort data while varying the catchability coefficient (q) and M simultaneously. The best fit to the data (the point where the residual variance was minimized) occurred at a M value of 0.12 (Bakkala and Wespestad 1984). This was also the value which provided the best fit to the observable population characteristics when M was profiled over a range of values in the stock assessment model using data up to 1992 (Wilderbuer 1992). Since then, natural mortality has been estimated as a free parameter in some of the stock assessment model runs which have been evaluated for the past five years. A natural mortality value of 0.12 is used for both sexes in the base model presented in this assessment.

Yellowfin sole maturity schedules were estimated from in-situ observations from two studies as discussed in a previous section (Table 4.10).

Parameters Estimated Inside the Assessment Model

The parameters estimated by the model are presented below:

Fishing mortality	Selectivity	Survey catchability	Year class strength	Spawner-recruit	Total
63	256	2	102	2	425

The increase in the number of parameters estimated in this assessment compared to last year (6) can be accounted for by the input of another year of fishery data and the entry of another year class into the observed population and four more sex-specific fishery selectivity parameters.

Year class strengths

The population simulation specifies the numbers-at-age in the beginning year of the simulation, the number of recruits in each subsequent year, and the survival rate for each cohort as it moves through the population over time using the population dynamics equations given in Table 4.11.

Selectivity

Fishery and survey selectivity was modeled separately for males and females using the two parameter formulation of the logistic function (Table 4.11). The model was run with an asymptotic selectivity curve for the older fish in the fishery and survey, but still was allowed to estimate the shape of the logistic curve for young fish. The oldest year classes in the surveys and fisheries were truncated at 20 and allowed to accumulate into the age category 20+ years. A single selectivity curve, for both males and females, was fit for all years of survey data.

Given that there have been annual changes in management, vessel participation and most likely gear selectivity, time-varying fishing selectivity curves were estimated. A logistic equation was used to model fishery selectivity and is a function of time-varying parameters specifying the age and slope at 50% selection, φ_t and η_t, respectively. The fishing selectivity (S^f) for age *a* and year *t* is modeled as,

$$S_{a,t}^{f} = \left[1 + e^{\eta_t (a - \varphi_t)}\right]^{-1}$$

where η_t and φ_t are time-varying and partitioned (for estimation) into parameters representing the mean and a vector of deviations (log-scale) conditioned to sum to zero. The deviations are constrained by a lognormal prior with a variance that was iteratively estimated. The process of iterating was to first set the variance to a high value (diffuse prior) of 0.5^2 and estimate the deviations. The next step was to compare the variability of model estimates. The variability of the model estimates were then rounded up slightly and fixed for subsequent runs. The 2015 values were fixed as the average of the 3 most recent years.

Fishing Mortality

The fishing mortality rates (F) for each age and year are calculated to approximate the catch weight by solving for F while still allowing for observation error in catch measurement. A large emphasis (300) was placed on the catch likelihood component to force the model to match the observed catch.

Survey Catchability

A past assessment (Wilderbuer and Nichol 2001) first examined the relationship between estimates of survey biomass and bottom water temperature. To better understand how water temperature may affect the catchability of yellowfin sole to the survey trawl, catchability was estimated for each year in the stock assessment model as:

$$q = e^{-\alpha + \beta T}$$

where q is catchability, T is the average annual bottom water temperature anomaly at survey stations less than 100 m, and α and β are parameters estimated by the model. The catchability equation has two parts. The $e^{-\alpha}$ term is a constant or time-independent estimate of q. The model estimate of $\alpha = -0.132$ indicates that $q > 1$ suggesting that yellowfin sole are herded into the trawl path of the net which is consistent with the experimental results for other flatfish species. The second term, $e^{\beta T}$ is a time-varying (annual) q which responds to metabolic aspects of herding or distribution (availability) which can vary annually with bottom water temperature. The result of incorporating bottom temperature to estimate annual q is shown in Figure 4.11 (for the base model).

Spawner-Recruit Estimation

Annual recruitment estimates from 1978-2010 were constrained to fit a Ricker (1958) form of the stock recruitment relationship as follows:

$$R = \alpha S e^{-\beta S}$$

where R is age 1 recruitment, S is female spawning biomass (t) the previous year, and α and β are parameters estimated by the model. The spawner-recruit fitting is estimated in a later phase after initial estimates of survival, numbers-at-age and selectivity are obtained.

Results

Model Evaluation

The model evaluation for this stock assessment involved a three-step process. The first step was to evaluate the productivity of the yellowfin sole stock by an examination of which sets of years to include for spawner-recruit fitting. The second step then evaluated the growth models presented in a previous section and the third step evaluated various hypothesized states of nature by fitting natural mortality and catchability estimates in various combinations.

The SSC determined in December 2006 that yellowfin sole would be managed under the Tier 1 harvest guidelines, and therefore future harvest recommendations would be based on MSY and F_{MSY} values calculated from a spawner-recruit relationship. MSY is an equilibrium concept and its value is dependent on both the spawner-recruit estimates which are assumed to represent the equilibrium stock size-recruitment relationship and the model used to fit the estimates. In the yellowfin sole stock assessment model, a Ricker form of the stock-recruit relationship was fit to various combinations of these data and estimates of F_{MSY} and B_{MSY} were calculated, assuming that the fit to the stock-recruitment data represents the long-term productivity of the stock.

For this assessment, 2 different stock-recruitment time-series were investigated: the full time-series 1955-2008 (Model A) and the post-regime shift era, 1978-2008 (Model B) (Fig. 4.12) (see Joint Plan Team recommendations for September 2012). Very different estimates of the long-term sustainability of the stock (F_{MSY} and B_{MSY}) are obtained, depending on which years of stock-recruitment data are included in the fitting procedure (Table 4.13). When the entire time-series from 1955-2008 was fit, the large recruitments that occurred at low spawning stock sizes in the 1960s and early 1970s determined that the yellowfin sole stock was most productive at a smaller stock size with the result that F_{MSY} (0.145) is higher than $F_{35\%}$ ($F_{35\%}$ = 0.135) and B_{MSY} is 392,000 (Model A). If we limit the analysis to consider only recruitments which occurred after the well-documented regime shift in 1977, a lower value of F_{MSY} is obtained (0.111) and B_{MSY} is 325,000 t. Table 4.13 indicates that the ABC values from the Model A harvest scenario for 2016 would be 98,000 t higher than Model B. Posterior distributions of F_{MSY} for these models indicate that this parameter is estimated with less uncertainty for Model A resulting in the reduced buffer between ABC and OFL relative to Model B (8% for Model B versus < 1% for Model A, Table 4.13 and Fig 4.13).

It is important for the Tier 1 calculations to identify which subset of the stock recruitment data is used. Using the full time series to fit the spawner recruit curve estimates that the stock is most productive at a small stock size. Thus MSY and F_{MSY} are relatively high values and B_{MSY} is a lower value. If the stock was productive in the past at a small stock size because of non-density dependent factors (environment), then reducing the stock size to low levels could be detrimental to the long-term sustainability of the stock if the environment, and thus productivity, had changed from the earlier period. Since observations of yellowfin sole recruitment at low stock sizes are not available from multiple time periods, it is uncertain if future recruitment events at low stock conditions would be as productive as during the late 1960s-early 1970s.

Given the uncertainty of the productivity of yellowfin sole at low spawning stock sizes, and because the AFSC policy for reference point time-series selection is to use the post 1977 regime shift values unless there is a compelling reason to do otherwise, the productivity of yellowfin sole in this assessment is estimated by fitting the 1977-2008 spawner-recruit data in the model (Model B).

The second step in the model evaluation is the evaluation of the growth model for yellowfin sole. Estimates of ABC, F_{ABC} and female spawning biomass for 2016 are shown below. Higher ABC can be realized from the three models that are linked to a year effect on growth (Models 1, 2 and 3).

	model 0	model 1	model 2	model 3
2016 FSB	810,500	702,200	678,700	659,000
2016 F_{ABC}	0.079	0.098	0.105	0.103
2016 ABC	167,500	211,700	215,500	226,400

Growth Model 1 was selected as the model of choice for this assessment since 1) It does not use time invariant growth as in Model 0 (unsupported by the growth data) but instead relies on the annually collected survey population length and age data to calculate annual estimates of length at age and weight-at-age. Weight-at-age for ages 11-20 were smoothed using a five year running average to reduce the variability in weights for these ages for 1982-2014, years when survey estimates of population-length-at age were available. The Model 3 fit to the data in Model 1are shown in Figure 4.15 from residual plots and also the Model 3 estimates of mean weight in relation to the annual bottom temperature anomalies.

The third step in the model evaluation for this assessment entails the use of a single structural model to consider the uncertainty in the key parameters M and catchability. This is the Model which has been the model of choice is the past 7 assessments and operates by fixing M at 0.12 for both sexes and then estimates q using the relationship between survey catchability and the annual average water temperature at the sea floor (from survey stations at less than 100 m). The other models used in the evaluation represented various combinations of estimating M or q as free parameters with different amounts of uncertainty in the parameter estimates (Wilderbuer et al. 2010). The results are detailed in those assessments and are not repeated here except for the following observations.

Modeling survey catchability as a nonlinear function of bottom water temperature returns q estimates > 1.0 for years when the bottom temperature is anomalously warm (greater than the mean temperature) and less than 1.0 when below the temperature mean. These values are consistent with our hypothesis that more fish are available to the survey in warm years relative to cooler years due to the timing of the annual spawning migration to nearshore areas that occurs sooner in warm years.

Experiments examining the bridle efficiency of the Bering Sea survey trawl indicate that yellowfin sole are herded into the trawl path from an area between the wing tips of the net and the point where the bridles contact the seafloor (Somerton and Munro 2001). The herding experiments suggest that the survey trawl catchability is greater than 1.0. The likelihood profile of q from the model indicated a small variance with a narrow range of likely values with a low probability of q being equal to the value of 1.0 in a past assessment (Wilderbuer and Nichol 2003).

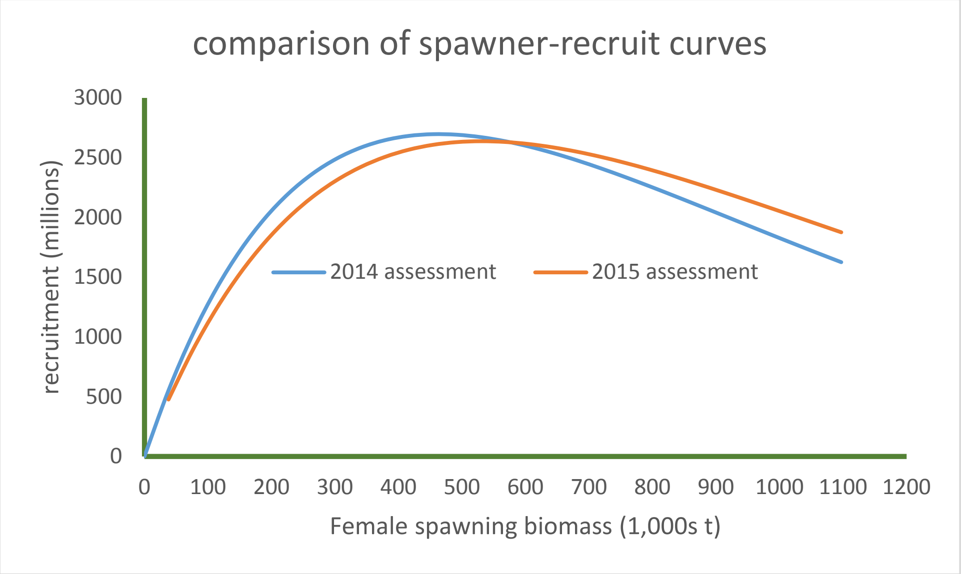
A model that allows M to be estimated as a free parameter for males with females fixed at 0.12 provided a better fit to the sex ratio estimated from the annual trawl survey age compositions than did the base model (both sexes fixed at M = 0.12). However, since the population sex ratio annually observed at the time of the survey is a function of the timing of the annual spawning in adjacent inshore areas, it is questionable that providing the best fit to these observations is really fitting the population sex ratio better. Thus, the model configuration which utilizes the relationship between annual seafloor temperature and survey catchability with M fixed at 0.12 for both sexes is used to base the assessment of the condition of the Bering Sea yellowfin sole resource for the 2015 fishing season.

Time Series Results

Before presenting the preferred model results, a brief consideration of the inputs and changes to the assessment methodology relative to last year (2014) is given. Primary updates were the catch, the fishery and survey age compositions from 2014, the 2015 survey biomass estimate, a small change in maturity and weight-at-age smoothing for ages 11-20. In their totality, these changes produced an ABC estimate (using the same assessment model as last year) that was 9% lower than last year, F_{ABC} that was 17% lower and FSB that was 8% larger. In order to understand the effect of the new data components on the 2015 results, a piece-wise example of the model results is presented. Part 1 updated the previous assessment model with the catch, the fishery and survey age compositions and the survey biomass. Part 2 added the revised maturity estimate requested by the SSC, and Part 3 included smoothing of the weight-at-age data for ages 11-20 and years 1982-2015 (also requested by the SSC in a past assessment review).

	2014	**Part 1**	**Part 2**	**Part 3**
F_{abc}	**0.117**	**0.111**	**0.111**	**0.097**
F_{ofl}	**0.125**	**0.120**	**0.120**	**0.105**
6+Biomass	**2,127,780**	**1,824,570**	**1824820**	**2,170,000**
ABC	**248,819**	**203.423**	**203,123**	**211,700**
OFL	**266,376**	**219,090**	**218,615**	**228,100**
FSB	**644,160**	**606,558**	**598,533**	**702,200**

For Part 1, the 2015 survey biomass estimate was 24% less than the 2014 estimate and had the effect of lowering the 2015 FSB estimate by 6% and the F_{ABC} by 5% relative to the 2014 estimate. The incorporation of the revised maturity schedule in Part 2 changed the estimates only slightly (since the new maturity and the one it replaced were very similar). Smoothing of the weight-at-age (5 year averaging) in Part 3 increased the FSB estimate relative to 2014 by 8% but also reduced the ABC estimate by 37,000 t due to the reduction in F_{ABC} by 17%. This reduction was due to refitting the spawner-recruit curve with the smoothed weight-at-age data which had the effect of flattening out the curve and moving MSY to the right (higher B_{msy}, lower F_{msy} for Tier 1 stocks).



The 2015 trawl survey point estimate decreased 24% from 2014. This resulted in lower model estimates of population numbers at age and biomass for the time-series back to the mid-1960s relative to last year's assessment. In addition, the large 2003 year class (12 years old in 2015) is present in the population, but now past their cohort maximum. The model results indicate the stock has been in a slowly declining condition since the mid-1980s. The estimates of total biomass and ABC are lower than those used to manage the stock in 2014. Seven of the past 10 years have had negative bottom temperature anomalies in the Bering Sea. 2015 was a warmer year relative to temperatures observed in 2006-2013 with an estimated value 1 deg. C above the long term mean. The temperature-dependent q adjustment for 2015 was 1.05.

Fishing Mortality and Selectivity

The assessment model estimates of the annual fishing mortality in terms of age-specific annual F and on fully selected ages are given in Tables 4.14 and 4.15, respectively. The full-selection F has averaged 0.08 over the period of 1978-2015 with a maximum of 0.12 in 1978 and a minimum in 2001 at 0.041. Selectivities estimated by the model (Table 4.16, Fig. 4.14) indicate that both sexes of yellowfin sole are 50% selected by the fishery at about age 9 and nearly fully selected by age 13, with annual variability.

Abundance Trend

The model estimates q at an average value of 0.98 for the period 1982-2015 which results in the model estimate of the 2015 age 2+ total biomass at 2,313,000 t (Table 4.17). Model results indicate that yellowfin sole total biomass (age 2+) was at low levels during most of the 1960s and early 1970s (700,000-1,000,000 t) after a period of high exploitation (Table 4.17, Fig. 4.16, center left panel). Sustained above average recruitment from 1967-76 combined with light exploitation resulted in a biomass increase to a peak of 3.4 million t by 1984. The population biomass has since been in a slow decline as the strong 1981 and 1983 year-classes have passed through the population with only the 1991, 1995 and 2003 year_classes at levels observed during the 1970s. The present biomass is estimated at 70% of the peak 1984 level.

The female spawning biomass has also declined since the peak in 1994, with a 2015 estimate of 697,200 t (34% decline). The spawning biomass has been in a gradual decline for the past 21 years and is 11% above the $B_{40\%}$ level and 1.6 times the B_{MSY} level (Fig. 4.16). The model estimate of yellowfin sole population numbers at age for all years is shown in Table 4.18 and the resulting fit to the observed fishery and survey age compositions input into the model are shown in the Figure 4.17. The fit to the trawl survey biomass estimates are shown in Figure 4.16. Allowing q to be correlated with annual bottom temperature provides a better fit to the bottom trawl survey estimates (Fig. 4.18). Table 4.19 lists the numbers of female spawners estimated by the model for all ages and years. The estimated average age of yellowfin sole in the population is 6.6 years for males and females.

Both the trawl survey and the stock assessment model indicate that the yellowfin sole resource increased during the 1970s and early 1980s to a peak level during the mid-1980s. The yellowfin sole population biomass slowly decreased over the 21 years since the mid-1990s as the majority of year-classes during those years were below average strength. Above-average recruitment from the strong 2003 year-class is expected to maintain the abundance of yellowfin sole at a level above B_{MSY} in the near future. The stock assessment projection model indicates a decreasing trend in female spawning biomass through 2023 if the fishing mortality rate continues at the same level as the average of the past 5 years (Fig. 4.22).

Recruitment Trends

The primary reason for the sustained increase in abundance of yellowfin sole during the 1970s and early 1980s was the recruitment of a series of stronger than average year classes spawned in 1967-76 (Figure 4.19 and Table 4.20). The 1981 year class was the strongest observed (and estimated) during the 47 year period analyzed and the 1983 year class was also very strong. Survey age composition estimates and the assessment model also estimate that the 1987 and 1988 year classes were average and the 1991 and 1995 year classes were above average. With the exception of these 4 year classes, recruitment from 15 of the following 19 years estimated from 1984-2005 (since the strong 1983 year-class) were below the 48 year average, which caused the population to gradually decline. The 2003 year-class has now been observed multiple times in the age compositions and are clearly a strong year class similar to some of the strong recruitment mentioned above and are contributing to the reservoir of spawning fish in the current population. In addition, recruitment from 2006-2008 may also be above average but at present, there is uncertainty due to a lack of repeated observations.

Historical Exploitation Rates
Based on results from the stock assessment model, annual average exploitation rates of yellowfin sole ranged from 3 to 8% of the total biomass since 1977, and have averaged 5% (Table 4.15). Posterior distributions of selected parameters from the preferred stock assessment model used in the assessment are shown in Figure 4.20. The values and standard deviations of some selected model parameters are listed in Table 4.21.

A within-model retrospective analysis is also included for the recommended assessment model where retrospective female spawning biomass is calculated by working backwards in time dropping data one year at a time (Fig. 4.21).

Harvest Recommendations

Since the peak value in 1984, estimates from the stock assessment model indicate the total biomass has slowly declined. The estimate of age 6+ total biomass for 2016 is 2,170,000 t.

The SSC has determined that yellowfin sole qualify as a Tier 1 stock and therefore the 2016 ABC is calculated using Tier 1 methodology. In 2006 the SSC selected the 1978-2001 data set for the Tier 1 harvest recommendation. Using this approach again for the 2016 harvest (now the 1978-2008 time-series) recommendation (Model B in Table 4.13 with growth option 1), the $F_{ABC} = F_{\text{harmonic mean}} = 0.098$.

The Tier 1 harvest level is calculated as the product of the harmonic mean of F_{MSY} and the geometric mean of the 2015 biomass estimate, as follows:

$$B_{gm} = e^{\ln \hat{B} - \frac{cv^2}{2}}$$

, where B_{gm} is the geometric mean of the 2016 biomass estimate, $\hat{B}$ is the point estimate of the 2016 biomass from the stock assessment model and cv^2 is the coefficient of variation of the point estimate (a proxy for sigma);

and

$$\bar{F}_{har} = e^{\ln \hat{F}_{msy} - \frac{\ln sd^2}{2}}$$

, where $\bar{F}_{har}$ is the harmonic mean, $\hat{F}_{msy}$ is the peak mode of the F_{MSY} distribution and sd^2 is the square of the standard deviation of the F_{MSY} distribution. This calculation gives a Tier 1 ABC harvest recommendation of **211,700 t** and an OFL of 228,100 t for 2016. This gives an 8% (16,400 t) buffer between ABC and OFL. The ABC value is 15% lower than last year, primarily due to a decreasing survey estimate and changes to the spawner-recruit curve from the weight-at-age modeling.

The stock assessment analysis must also consider harvest limits, usually described as overfishing fishing mortality levels with corresponding yield amounts. Amendment 56 to the BSAI FMP sets the Tier 1 harvest limit at the F_{MSY} fishing mortality value. The overfishing fishing mortality values, ABC fishing mortality values and their corresponding yields are given as follows:

Harvest level	F value	2016 Yield
Tier 1 F_{OFL} = F_{MSY}	**0.105**	**228,100 t**
Tier 1 F_{ABC} = $F_{harmonic\ mean}$	**0.098**	**211,700 t**

Status Determination

A standard set of projections is required for each stock managed under Tiers 1, 2, or 3 of Amendment 56. This set of projections encompasses seven harvest scenarios designed to satisfy the requirements of Amendment 56, the National Environmental Policy Act, and the Magnuson-Stevens Fishery Conservation and Management Act (MSFCMA).

For each scenario, the projections begin with the vector of 2015 numbers at age estimated in the assessment. This vector is then projected forward to the beginning of 2016 using the schedules of natural mortality and selectivity described in the assessment and the best available estimate of total (year-end) catch for 2015. In each subsequent year, the fishing mortality rate is prescribed on the basis of the spawning biomass in that year and the respective harvest scenario. In each year, recruitment is drawn from an inverse Gaussian distribution whose parameters consist of maximum likelihood estimates determined from recruitments estimated in the assessment. Spawning biomass is computed in each year based on the time of peak spawning and the maturity and weight schedules described in the assessment. Total catch is assumed to equal the catch associated with the respective harvest scenario in all years. This projection scheme is run 1000 times to obtain distributions of possible future stock sizes, fishing mortality rates, and catches.

Five of the seven standard scenarios will be used in an Environmental Assessment prepared in conjunction with the final SAFE. These five scenarios, which are designed to provide a range of harvest alternatives that are likely to bracket the final TAC for 2016, are as follows ("*max* F_{ABC}" refers to the maximum permissible value of F_{ABC} under Amendment 56):

> *Scenario 1*: In all future years, F is set equal to *max* F_{ABC}. (Rationale: Historically, TAC has been constrained by ABC, so this scenario provides a likely upper limit on future TACs.)
>
> *Scenario 2*: In all future years, F is set equal to a constant fraction of *max* F_{ABC}, where this fraction is equal to the ratio of the F_{ABC} value for 2016 recommended in the assessment to the *max* F_{ABC} for 2016. (Rationale: When F_{ABC} is set at a value below *max* F_{ABC}, it is often set at the value recommended in the stock assessment.)
>
> *Scenario 3*: In all future years, F is set equal to 50% of max F_{ABC}. (Rationale: This scenario provides a likely lower bound on F_{ABC} that still allows future harvest rates to be adjusted downward when stocks fall below reference levels.)
>
> *Scenario 4*: In all future years, F is set equal to the 2011-2015 average F. (Rationale: For some stocks, TAC can be well below ABC, and recent average F may provide a better indicator of F_{TAC} than F_{ABC}.)
>
> *Scenario 5*: In all future years, F is set equal to zero. (Rationale: In extreme cases, TAC may be set at a level close to zero.)

Two other scenarios are needed to satisfy the MSFCMA's requirement to determine whether a stock is currently in an overfished condition or is approaching an overfished condition. These two scenarios are as follow (for Tier 3 stocks, the MSY level is defined as $B_{35\%}$):

> *Scenario 6*: In all future years, F is set equal to F_{OFL}. (Rationale: This scenario determines whether a stock is overfished. If the stock is expected to be above its MSY level in 2014 and above its MSY level in 2027 under this scenario, then the stock is not overfished.)
>
> *Scenario 7*: In 2016 and 2017, F is set equal to *max* F_{ABC}, and in all subsequent years, F is set equal to F_{OFL}. (Rationale: This scenario determines whether a stock is approaching an overfished condition. If the stock is expected to be above its MSY level in 2028 under this scenario, then the stock is not approaching an overfished condition.)

Simulation results shown in Table 4.22 indicate that yellowfin sole are not currently overfished and are not approaching an overfished condition. The projection of yellowfin sole female spawning biomass through 2026 is shown in Figure 4.22 and a phase plane figure of the estimated time-series of yellowfin sole female spawning biomass relative to the harvest control rule is shown in Figure 4.23.

Scenario Projections and Two-Year Ahead Overfishing Level

In addition to the seven standard harvest scenarios, Amendments 48/48 to the BSAI and GOA Groundfish Fishery Management Plans require projections of the likely OFL two years into the future. The 2015 numbers at age from the stock assessment model are projected to 2016 given the 2015 catch and then a 2016 catch of 150,000 t is applied to the projected 2016 population biomass to obtain the 2017 OFL.

Tier 1 Projection

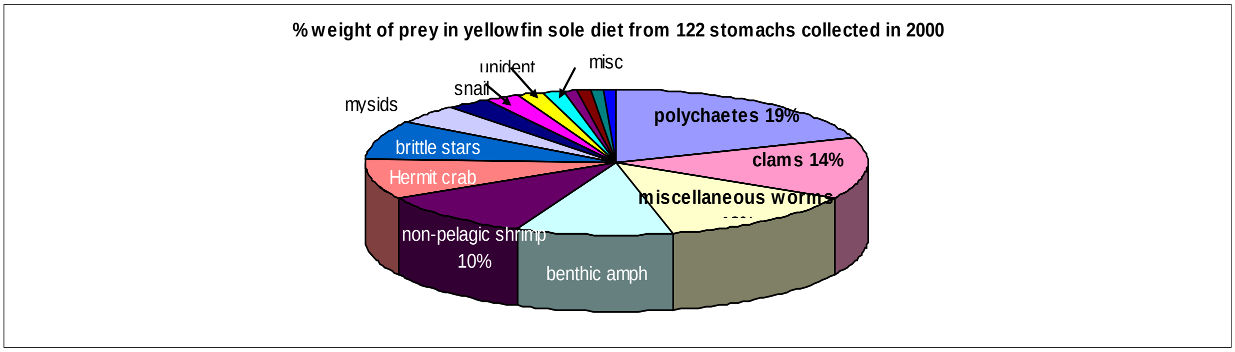
Year	**Catch**	**SSB**	**Geometric mean 6+ total biomass**	**ABC**	**OFL**
2016	150,000	702,200	2,170,000	211,700	228,100
2017	150,000	696,200	2,086,100	203,500	219,200

Ecosystem Considerations

Ecosystem Effects on the stock

1) Prey availability/abundance trends

Yellowfin sole diet by life stage varies as follows: Larvae consume plankton and algae, early juveniles consume zooplankton, late juvenile stage and adults prey includes bivalves, polychaetes, amphipods, mollusks, euphausids, shrimps, brittle stars, sculpins and miscellaneous crustaceans. Information is not available to assess the abundance trends of the benthic infauna of the Bering Sea shelf. The original description of infaunal distribution and abundance by Haflinger (1981) resulted from sampling conducted in 1975 and 1976 and has not been re-sampled since. The large populations of flatfish which have occupied the middle shelf of the Bering Sea over the past twenty-five years for summertime feeding do not appear food-limited. These populations have fluctuated due to the variability in recruitment success which suggests that the primary infaunal food source has been at an adequate level to sustain the yellowfin sole resource.



2) Predator population trends
As juveniles, it is well-documented from studies in other parts of the world that flatfish are prey for shrimp species in near shore areas. This has not been reported for Bering Sea yellowfn sole due to a lack of juvenile sampling and collections in near shore areas, but is thought to occur. As late juveniles they have been found in stomachs of Pacific cod and Pacific halibut; mostly on small yellowfin sole ranging from 7 to 25 cm standard length..

Past, present and projected future population trends of these predator species can be found in their respective SAFE chapters in this volume and also from Annual reports compiled by the International Pacific Halibut Commission. Encounters between yellowfin sole and their predators may be limited since their distributions do not completely overlap in space and time.

3) Changes in habitat quality
Changes in the physical environment which may affect yellowfin sole distribution patterns, recruitment success and migration timing patterns are catalogued in the Ecosystem Considerations Report of this SAFE report. Habitat quality may be enhanced during years of favorable cross-shelf advection (juvenile survival) and warmer bottom water temperatures with reduced ice cover (higher metabolism with more active feeding).

Fishery Effects on the ecosystem

1) The yellowfin sole target fishery contribution to the total bycatch of other target species is shown for 1992-2014 in Table 4.23. The catch of non-target species from 2003-2014 is shown in Table 4.24. The yellowfin sole target fishery contribution to the total bycatch of prohibited species is shown for 2012 and 2013 in Table 13 of the Economic SAFE (Appendix C) and is summarized for 2013 as follows:

Prohibited species	Yellowfin sole fishery % of total bycatch
Halibut mortality	33.4
Herring	2.7
Red King crab	8
C. bairdi	58.5
Other Tanner crab	77.9
Salmon	<1

2) Relative to the predator needs in space and time, the yellowfin sole target fishery has a low selectivity for fish 7-25 cm and therefore has minimal overlap with removals from predation.

3) The target fishery is not perceived to have an effect on the amount of large size target fish in the population due to its history of light to moderate exploitation (6%) over the past 30 years. Population age composition data indicate a large 20+ age group.

4) Yellowfin sole fishery discards are presented in the Catch History section.

5) It is unknown what effect the fishery has had on yellowfin sole maturity-at-age and fecundity.

6) Analysis of the benthic disturbance from the yellowfin sole fishery is available in the Preliminary draft of the Essential Fish Habitat Environmental Impact Statement.

Ecosystem effects on yellowfin sole

Indicator	Observation	Interpretation	Evaluation
Prey availability or abundance trends			
Benthic infauna	Stomach contents	Stable, data limited	Unknown
Predator population trends			
Fish (Pacific cod, halibut, skates)	Stable	Possible increases to yellowfin sole mortality	
Changes in habitat quality			
Temperature regime	Cold years yellowfin sole catchability and herding may decrease, timing of migration may be prolonged	Likely to affect surveyed stock	No concern (dealt with in model)
Winter-spring environmental conditions	Affects pre-recruit survival	Probably a number of factors	Causes natural variability

***Yellowfin sole* effects on ecosystem**

Indicator	Observation	Interpretation	Evaluation
Fishery contribution to bycatch			
Prohibited species	Stable, heavily monitored	Minor contribution to mortality	No concern
Forage (including herring, Atka mackerel, cod, and pollock)	Stable, heavily monitored	Bycatch levels small relative to forage biomass	No concern
HAPC biota	Low bycatch levels of (spp)	Bycatch levels small relative to HAPC biota	No concern
Marine mammals and birds	Very minor direct-take	Safe	No concern
Sensitive non-target species	Likely minor impact	Data limited, likely to be safe	No concern
Fishery concentration in space and time	Low exploitation rate	Little detrimental effect	No concern
Fishery effects on amount of large size target fish	Low exploitation rate	Natural fluctuation	No concern
Fishery contribution to discards and offal production	Stable trend	Improving, but data limited	Possible concern
Fishery effects on age-at-maturity and fecundity	Unknown	NA	Possible concern

Data Gaps and Research Priorities

Isolation by distance genetic study to define stock structure in the planning stage. NPRB proposal to collect maturity in the northern Bering Sea for comparison with recent SE Bering Sea shelf samples.

17	.997	1.0	1.0
18	1.0	1.0	1.0
19	1.0	1.0	1.0
20	1.0	1.0	1.0

Table 4.11. Key equations used in the population dynamics model.

$N_{t,1} = R_t = R_0 e^{\tau_t}, \quad \tau_t \sim N(0,\delta^2{}_R)$	Recruitment 1956-75
$N_{t,1} = R_t = R_\gamma e^{\tau_t}, \quad \tau_t \sim N(0,\delta^2{}_R)$	Recruitment 1976-96
$C_{t,a} = \frac{F_{t,a}}{Z_{t,a}}\left(1 - e^{-z_{t,a}}\right)N_{t,a}$	Catch in year *t* for age *a* fish
$N_{t+1,a+1} = N_{t,a}e^{-z_{t,a}}$	Numbers of fish in year *t+1* at age *a*
$N_{t+1,A} = N_{t,A-1}e^{-z_{t,A-1}} + N_{t,A}e^{-z_{t,A}}$	Numbers of fish in the “plus group”
$S_t = \sum N_{t,a}W_{t,a}\phi_a$	Spawning biomass
$Z_{t,a} = F_{t,a} + M$	Total mortality in year *t* at age *a*
$F_{t,a} = s_a \mu^F \exp^{\varepsilon^F{}_t}, \quad \varepsilon^F{}_t \sim N(o,\sigma^2{}_F)$	Fishing mortality
$s_a = \frac{1}{1+\left(e^{-\alpha+\beta a}\right)}$	Age-specific fishing selectivity
$C_t = \sum C_{t,a}$	Total catch in numbers
$P_{t,a} = {}^{C_{t,a}}\!/_{C_t}$	Proportion at age in catch
$SurB_t = q\sum N_{t,a}W_{t,a}v_a$	Survey biomass

Table 4.11—continued.

$qprior = \lambda \frac{0.5(\ln q_{est,t} - \ln q_{prior})^2}{\sigma_q^2}$	survey catchability prior (when estimated)
$mprior = \lambda \frac{0.5(\ln m_{est} - \ln m_{prior})^2}{\sigma_m^2}$	natural mortality prior (when estimated)
$reclike = \lambda(\sum_{i=1965}^{endyear} \bar{R} - R_i)^2 + \sum_{a=1}^{20} (\bar{R}_{init} - R_{init,a})^2 + \frac{1}{2((\sum_{i=1965}^{endyear} \bar{R} - R_i)\frac{1}{n+1})})$	recruitment likelihood
$catchlike = \lambda \sum_{i=startyear}^{endyear} (\ln C_{obs,i} - \ln C_{est,i})^2$	catch likelihood
$surveylike = \lambda \frac{(\ln B - \ln \hat{B})^2}{2\sigma^2}$	survey likelihood
$SurvAgelike = \sum_{i,t} m_t P_{t,a} \ln \frac{\hat{P}_{t,a}}{P_{t,a}}$	survey age composition likelihood
$FishAgelike = \sum_{i,t} m_t P_{t,a} \ln \frac{\hat{P}_{t,a}}{P_{t,a}}$	fishery age composition likelihood

Table 4.12. Variables used in the population dynamics model.

Variables	
R_t	Age 1 recruitment in year *t*
R_0	Geometric mean value of age 1 recruitment, 1956-75
R_γ	Geometric mean value of age 1 recruitment, 1976-2014
τ_t	Recruitment deviation in year *t*
$N_{t,a}$	Number of fish in year *t* at age *a*
$C_{t,a}$	Catch numbers of fish in year *t* at age *a*
$P_{t,a}$	Proportion of the numbers of fish age *a* in year *t*
C_t	Total catch numbers in year *t*
$W_{t,a}$	Mean body weight (kg) of fish age *a* in year *t*
ϕ_a	Proportion of mature females at age *a*
$F_{t,a}$	Instantaneous annual fishing mortality of age *a* fish in year *t*
M	Instantaneous natural mortality, assumed constant over all ages and years
$Z_{t,a}$	Instantaneous total mortality for age *a* fish in year *t*
s_a	Age-specific fishing gear selectivity
μ^F	Median year-effect of fishing mortality
ε_t^F	The residual year-effect of fishing mortality
ν_a	Age-specific survey selectivity
α	Slope parameter in the logistic selectivity equation
β	Age at 50% selectivity parameter in the logistic selectivity equation
σ_t	Standard error of the survey biomass in year t

Table 4.13. Models evaluated for stock productivity in the 2014 stock assessment of yellowfin sole

	Model A	**Model B**
Years included	1955-2008	1978-2008
Fmsy	0.147	0.111
Bmsy (t)	333,000	435,000
ABC (t)	313,400	215,545
OFL (t)	315,500	228,800
Buffer between ABC and OFL	<1%	6%

Table 4-14. Model estimates of annual average fishing mortality for male and female yellowfin sole.

Table 4.22. Projections of yellowfin sole female spawning biomass (1,000s t), catch (1,000s t) and full selection fishing mortality rate for seven future harvest scenarios.

Scenarios 1 and 2
Maximum Tier 3 ABC harvest permissible

Year	Female spawning biomass	catch	F
2015	699.339	121.995	0.08
2016	703.42	172.962	0.11
2017	691.616	169.275	0.11
2018	677.745	163.86	0.11
2019	658.692	155.31	0.11
2020	634.424	147.228	0.11
2021	605.855	137.859	0.11
2022	583.698	131.226	0.10
2023	574.687	130.464	0.10
2024	576.888	133.801	0.10
2025	583.557	138.164	0.10
2026	594.587	142.786	0.10
2027	605.585	146.623	0.11
2028	613.965	149.114	0.11

Scenario 4
1/2 Maximum Tier 3 ABC harvest permissible

Year	Female spawning biomass	catch	F
2015	699.339	121.995	0.08
2016	716.320	86.479	0.05
2017	741.962	89.160	0.05
2018	763.529	90.207	0.05
2019	776.602	89.107	0.05
2020	780.073	87.579	0.05
2021	773.006	87.210	0.05
2022	764.490	87.687	0.05
2023	764.663	89.313	0.05
2024	774.710	91.549	0.05
2025	788.467	93.669	0.05
2026	807.533	95.853	0.05
2027	826.989	97.905	0.05
2028	843.036	99.529	0.05

Scenario 3
Harvest at average F over the past 5 years

Year	Female spawning biomass	catch	F
2015	699.339	121.995	0.08
2016	708.650	138.233	0.09
2017	705.606	178.160	0.12
2018	688.067	171.570	0.12
2019	665.333	161.821	0.12
2020	637.640	152.707	0.12
2021	605.411	147.218	0.12
2022	578.066	144.537	0.12
2023	562.881	144.658	0.12
2024	559.079	146.391	0.12
2025	560.825	148.348	0.12
2026	568.181	150.575	0.12
2027	576.788	152.733	0.12
2028	583.862	154.348	0.12

Scenario 5
No fishing

Year	Female spawning biomass	catch	F
2015	699.339	121.995	0.08
2016	728.820	0	0
2017	793.505	0	0

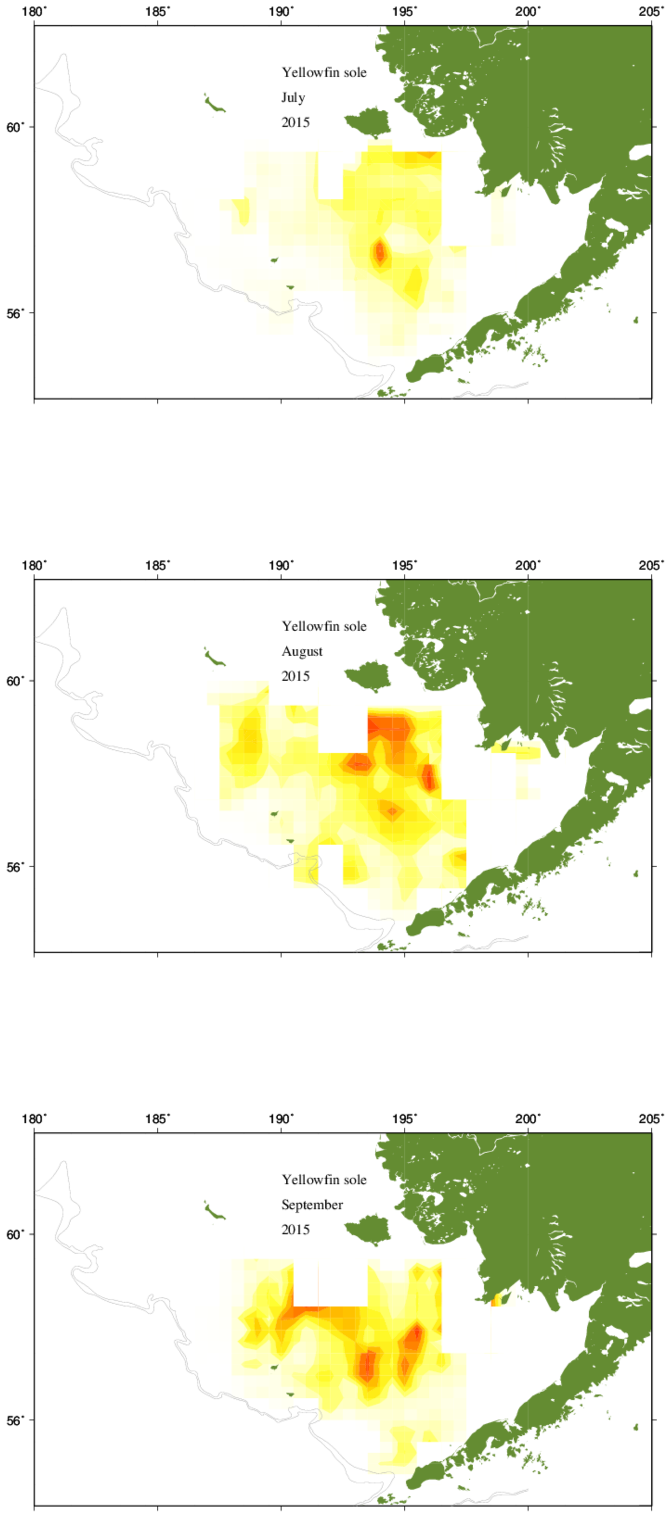

Figure 4.4— (Fishery locations by month).

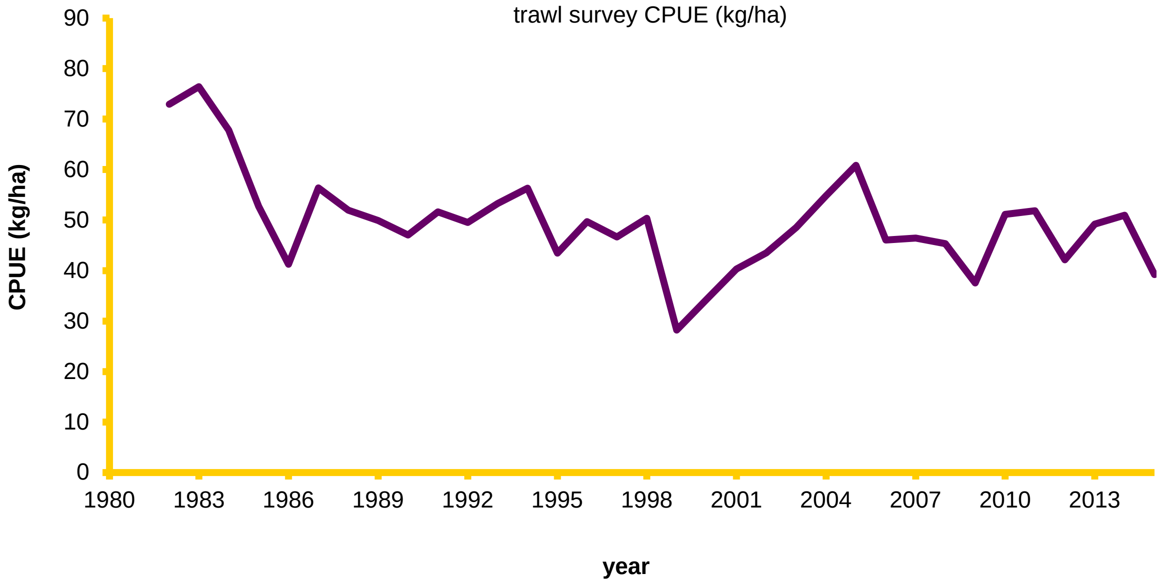

Figure 4.5.--Yellowfn sole CPUE (catch per unit effort in kg/ha) from the annual Bering Sea shelf trawl surveys, 1982-2015.

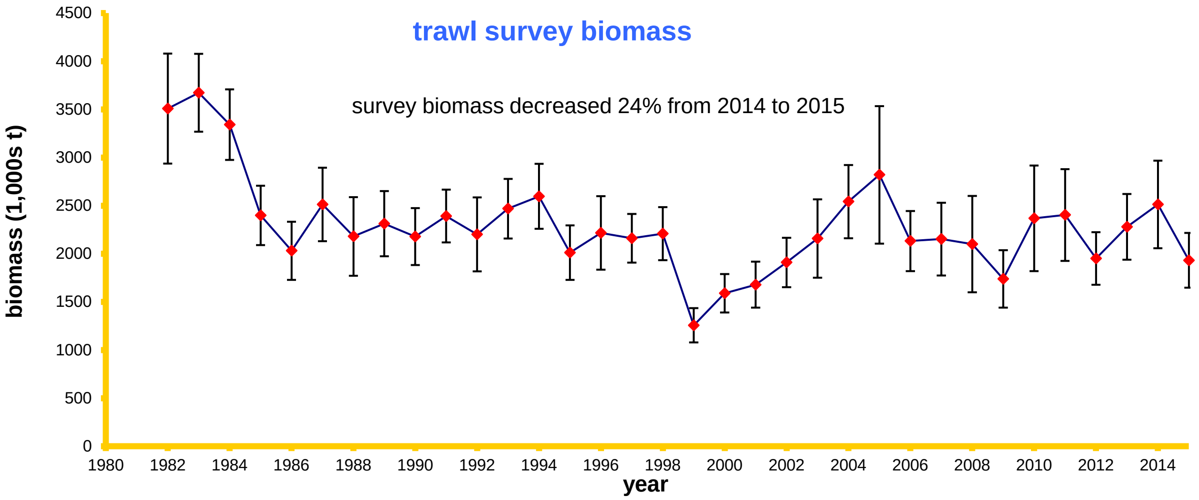

Figure 4.6.--Annual bottom trawl survey biomass point-estimates and 95% confidence intervals for yellowfin sole, 1982-2015.

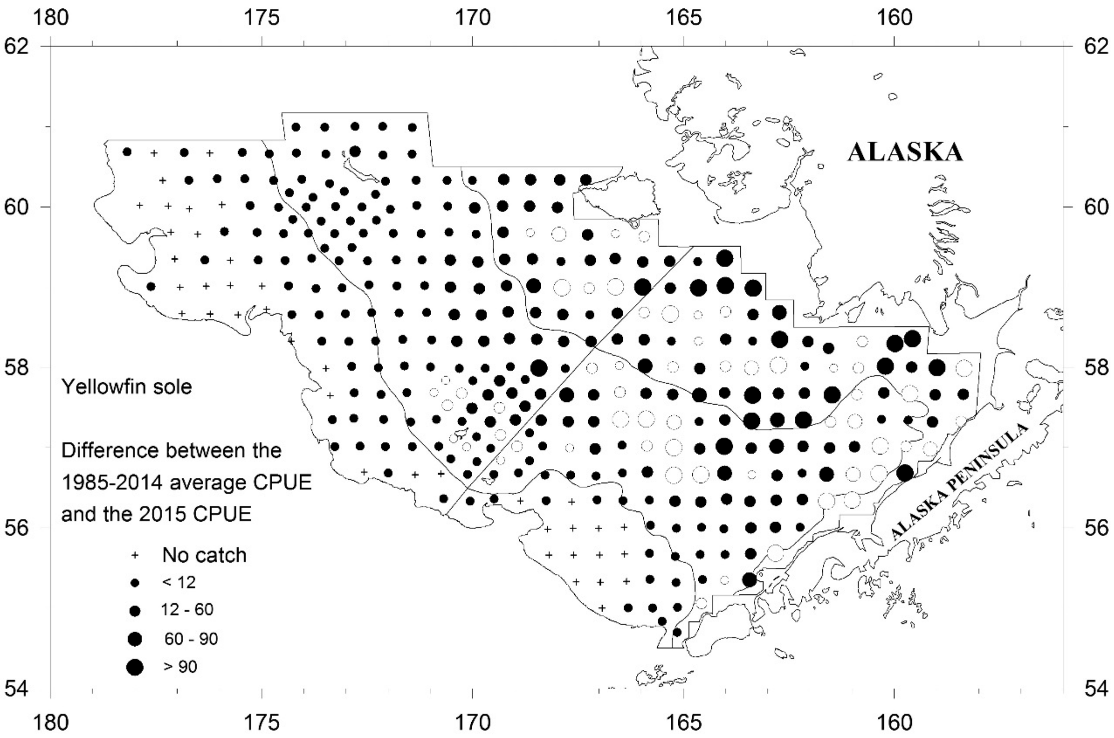

Figure 4.7.--Difference between the 1985-2014 average trawl survey CPUE for yellowfin sole and the 2015 survey CPUE. Open circles indicate that the magnitude of the catch was greater in 2015 than the long-term average, closed circles indicate the catch was greater in the long-term average than in 2015.

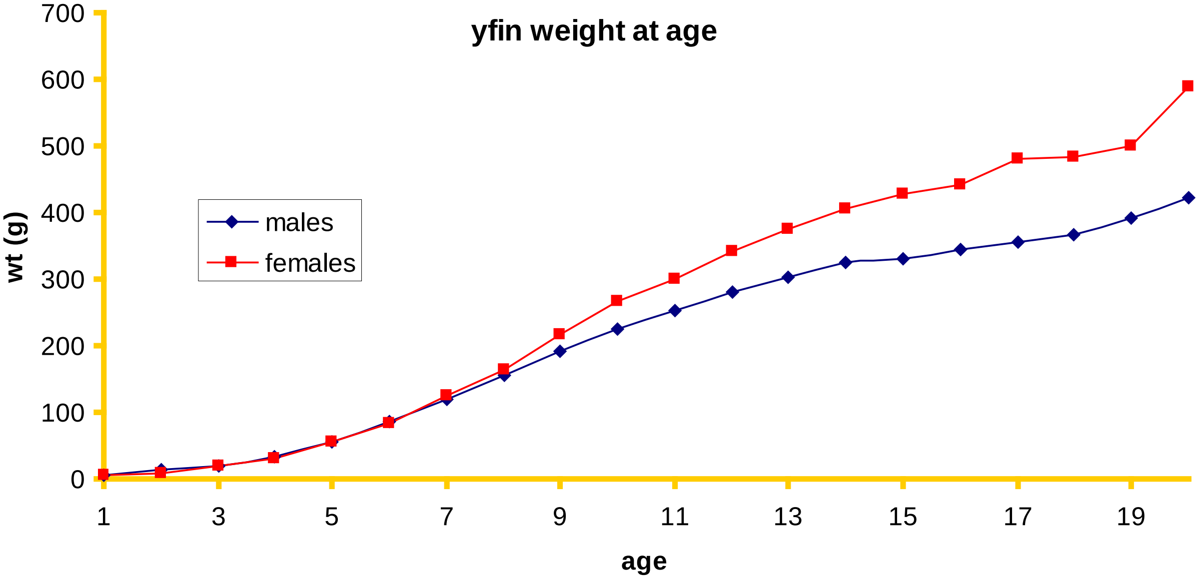

Figure 4.8--Estimates of average yellowfin sole weight-at-age (g) from trawl survey observations.

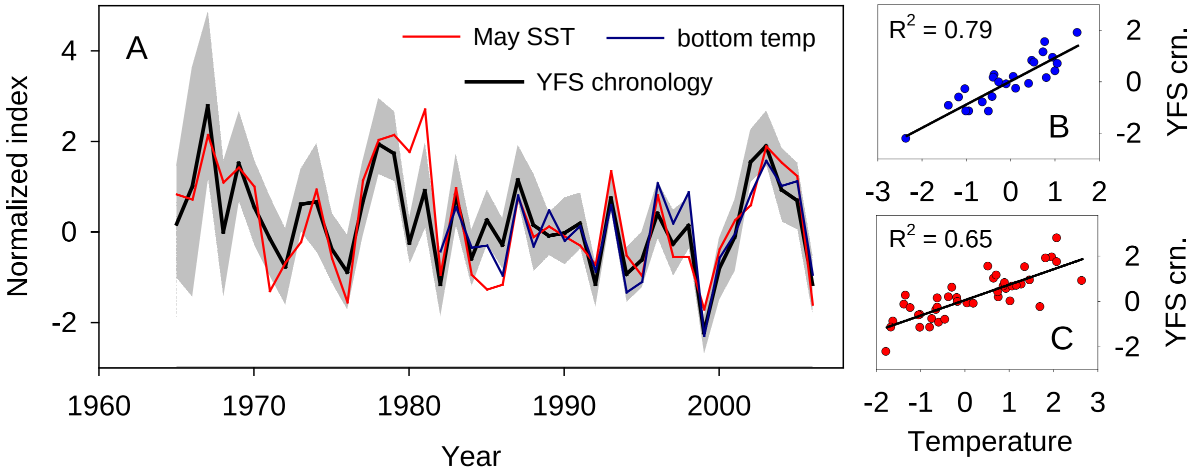

Figure 4.9--Master chronology for yellowfin sole and time series of mean summer bottom temperature and May sea surface temperature for the southeastern Bering Sea (Panel A). All data re normalized to a mean of 0 and standard deviation of 1. Correlations of chronologies with bottom temperature and sea surface temperature are shown in panels B and C, respectively. From Matta et al. 2010.

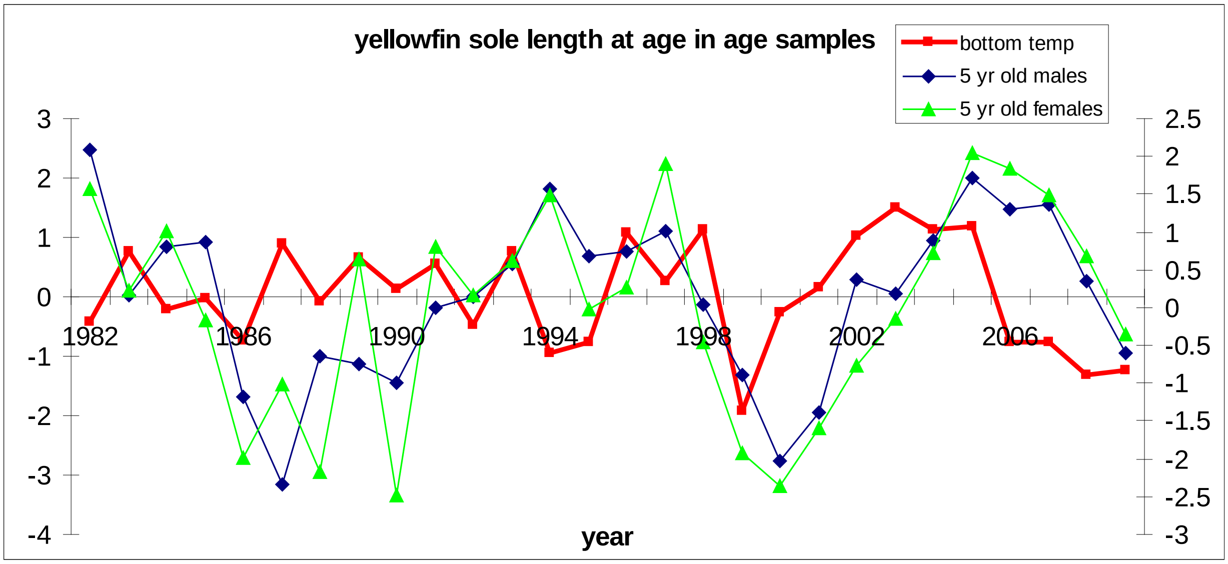

Figure 4.10—Yellowfin sole length-at-age anomalies, for males and females, and bottom temperature anomalies. Correspondence in these residuals is apparent with a 2-3 year lag effect from the mid-1990s to 2009. Late 1980s and early 1990s pattern may be a density-dependent response in growth from the large 1981 and 1983 year-classes.

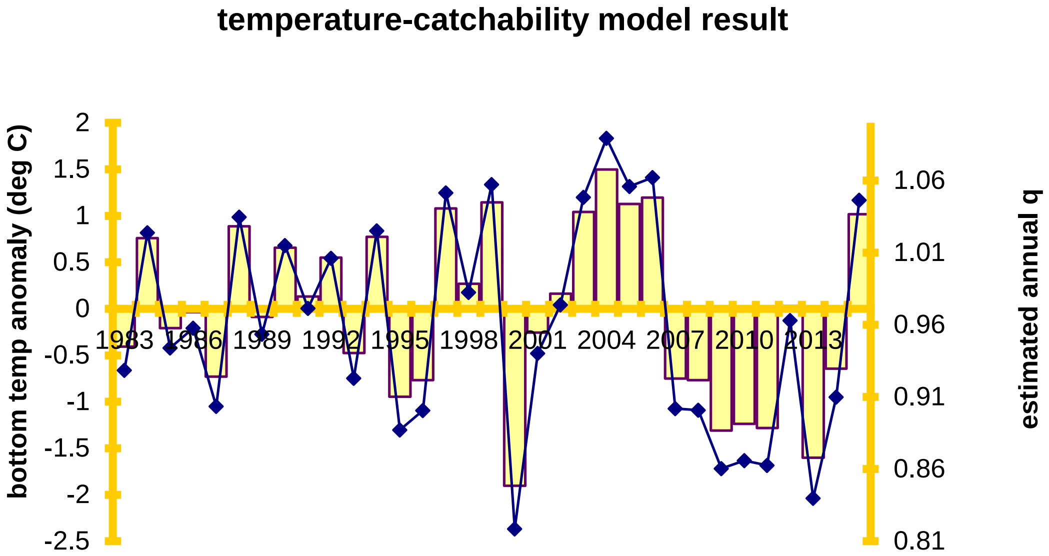

Figure 4.11.--Average bottom water temperature from stations less than or equal to 100 m in the Bering Sea trawl survey (bars) and the stock assessment model estimate of q for each year 1982-2015.

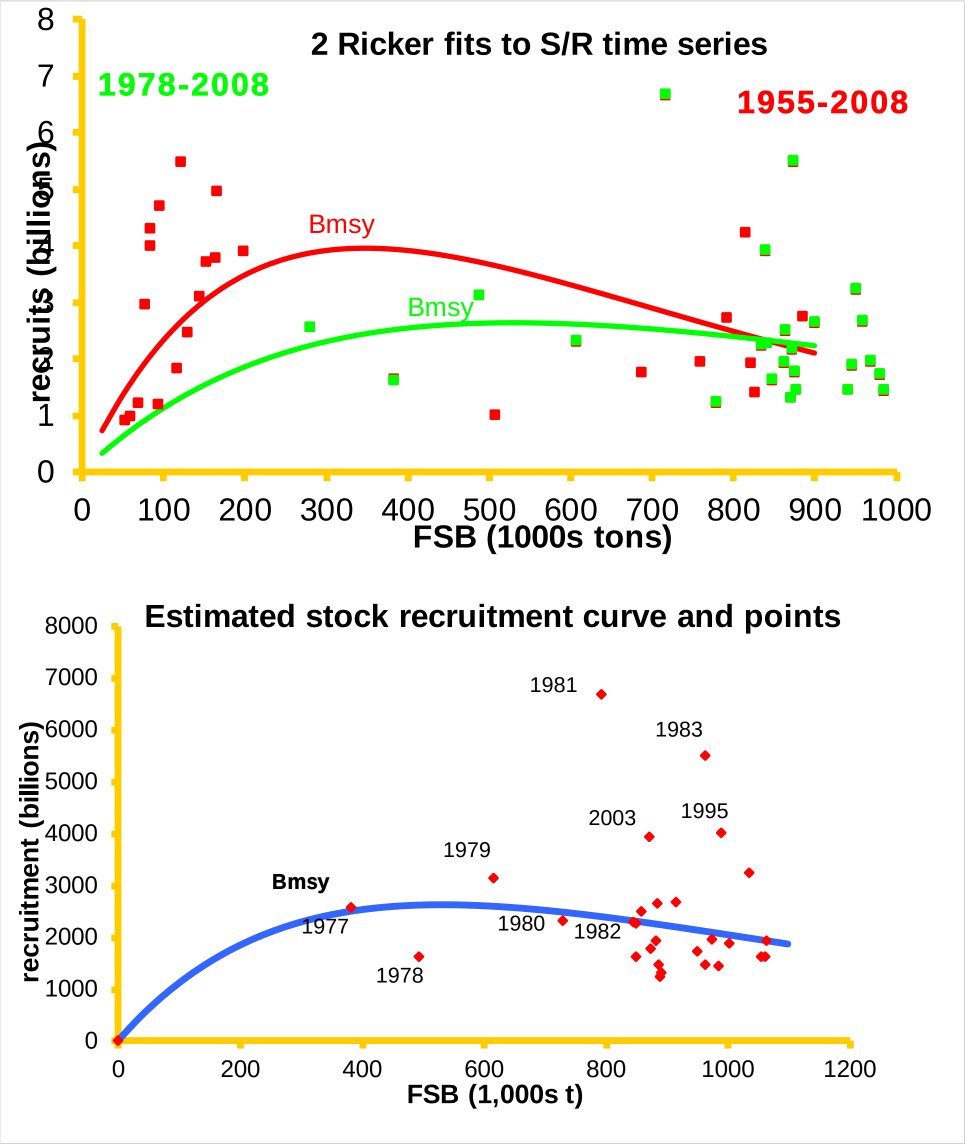

Figure 4.12--Fit of the Ricker (1958) stock recruitment model to two distinct stock recruitment time-series data sets (top panel), and the fit to the assessment preferred model (model B, lower panel).

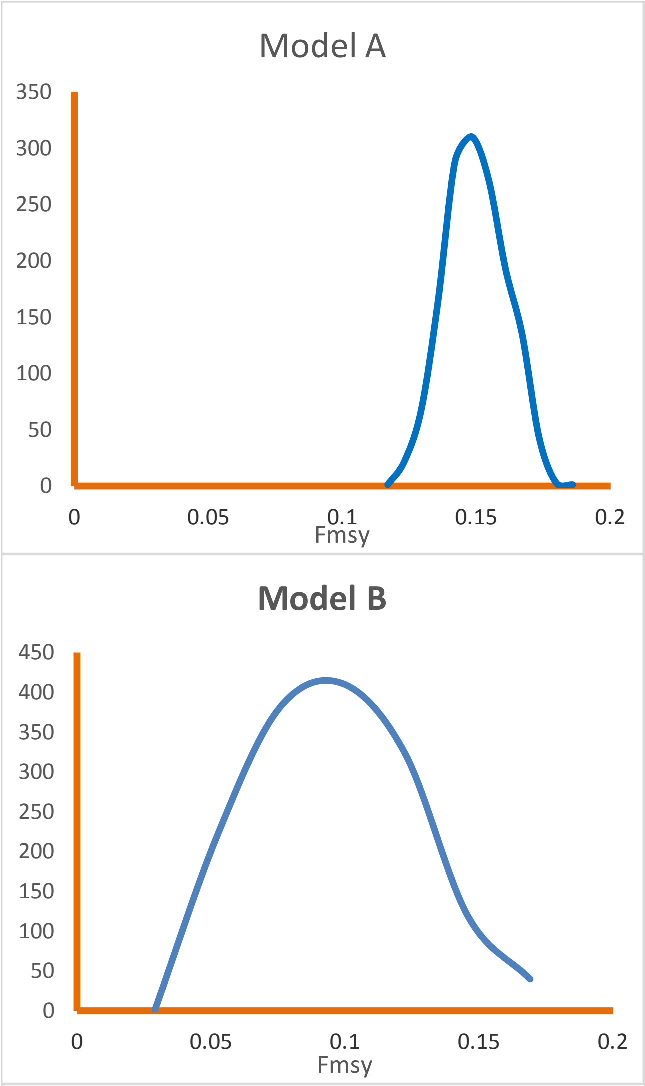

Figure 4.13--Posterior distributions of F_{msy} for the two models considered in the stock productivity analysis.

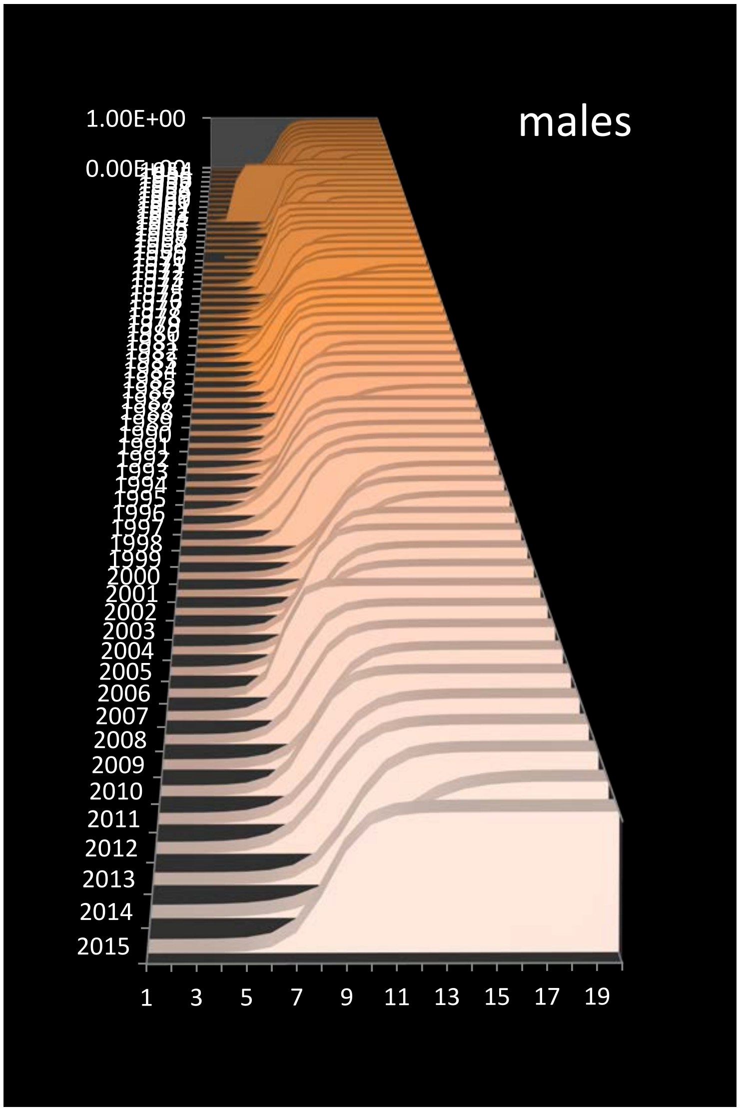

Figure 4.14a--Estimated male fishery selectivity by age and year.

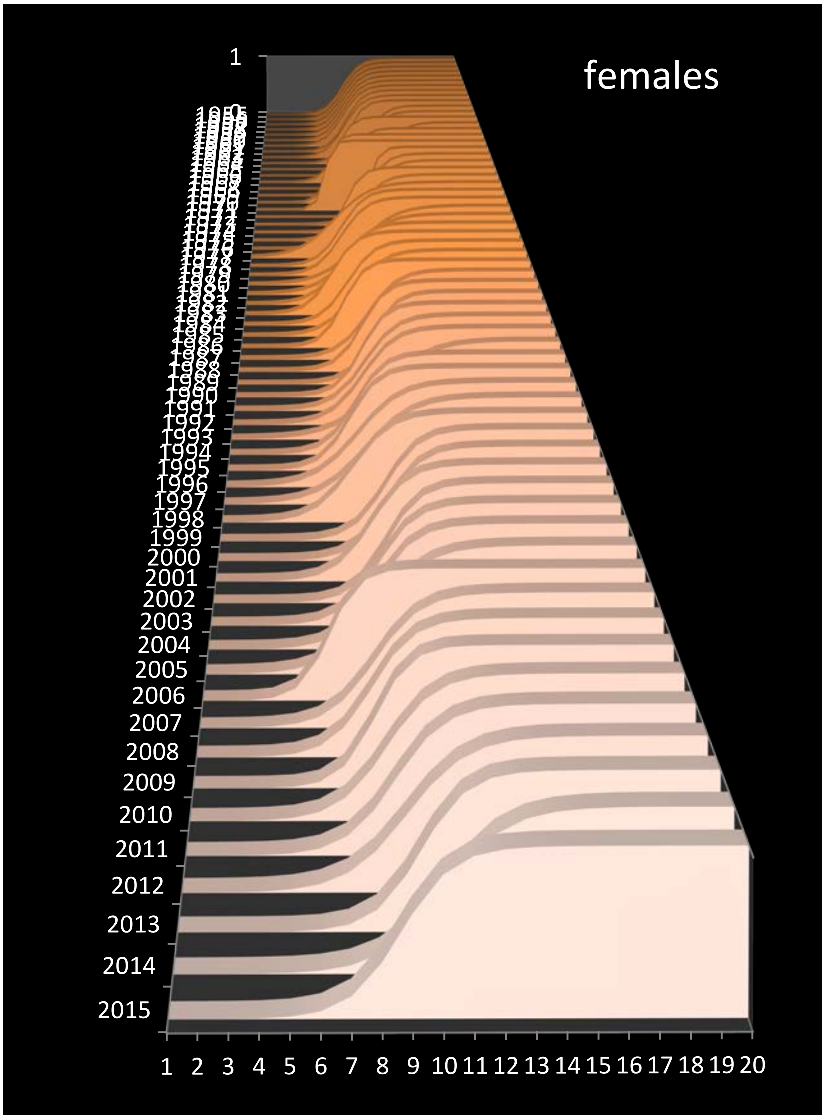

Figure 4.14b.--Estimated female fishery selectivity by age and year.

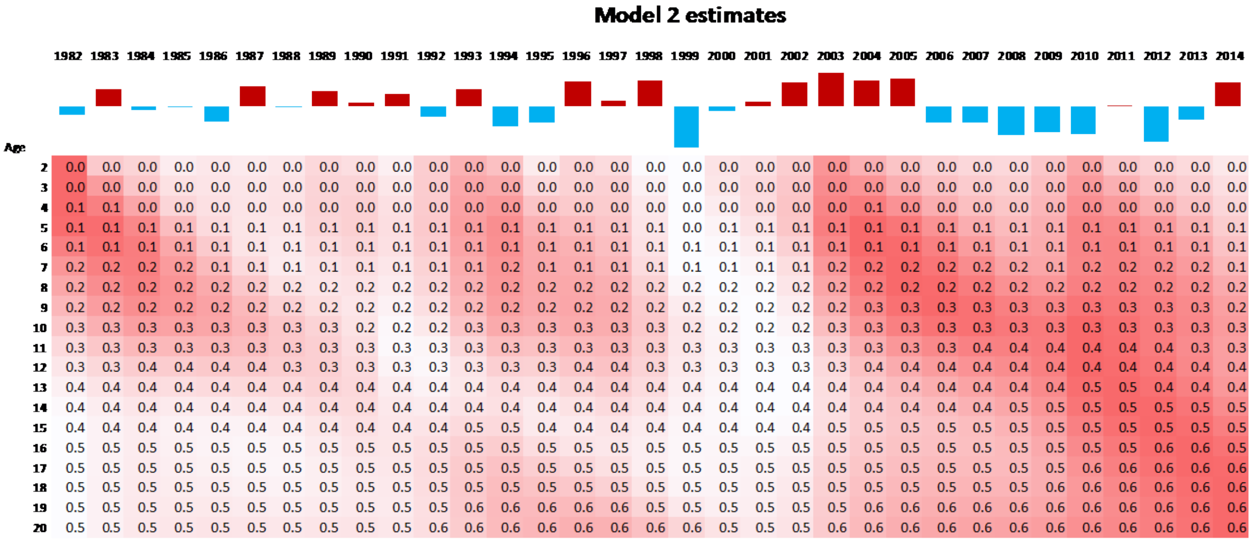
Figure 4.15—Results show the temperature anomalies (second row at top and as bars repeated at the top and in middle) and model 3 estimates of mean weights (kg) (top matrix) and observed values (Model 1, bottom matrix) by age and year. Shadings within each matrix reflects relative weight-at-age (within a row) with darker red being heavier than average.



Model 2 estimates

Figure 4-15 (continued). Results show the temperature anomalies (second row at top and as bars repeated at the top and in middle) and **model 2** estimates of mean weights (top matrix) and observed values (bottom matrix) by age and year. Shadings within each matrix reflects relative weight-at-age (within a row) with darker red being heavier than average.

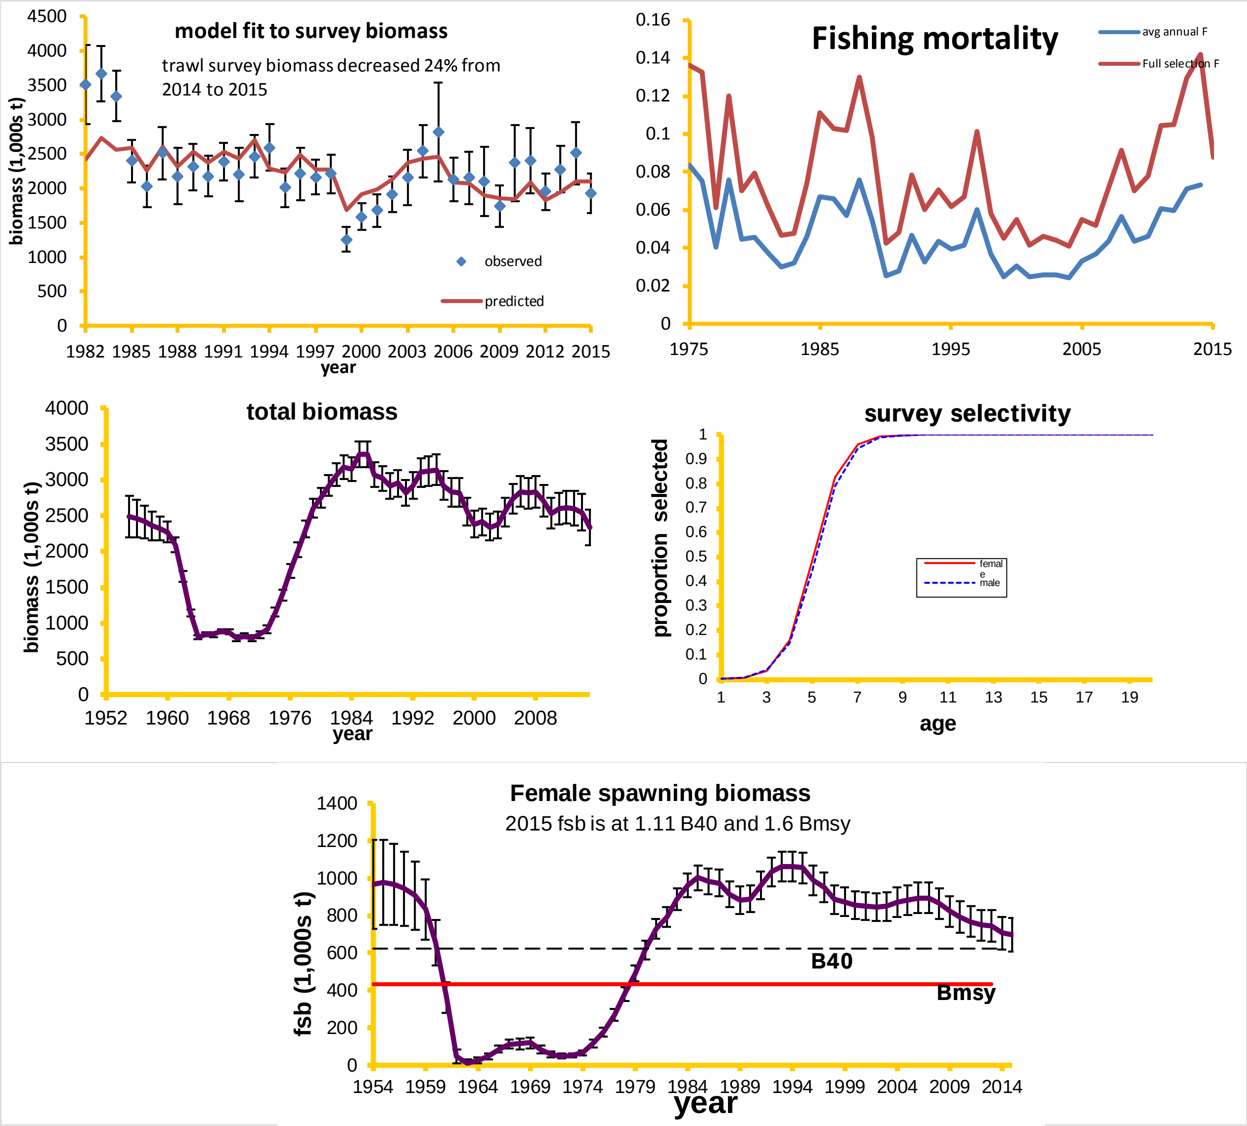

Figure 4.16. Model fit to the survey biomass estimates (top left panel), model estimate of the full selection fishing mortality rate throughout the time-series (top right panel), model estimate of total biomass (middle left panel), the model estimate of survey selectivity (middle right panel) and the estimate of female spawning biomass (bottom left panel).

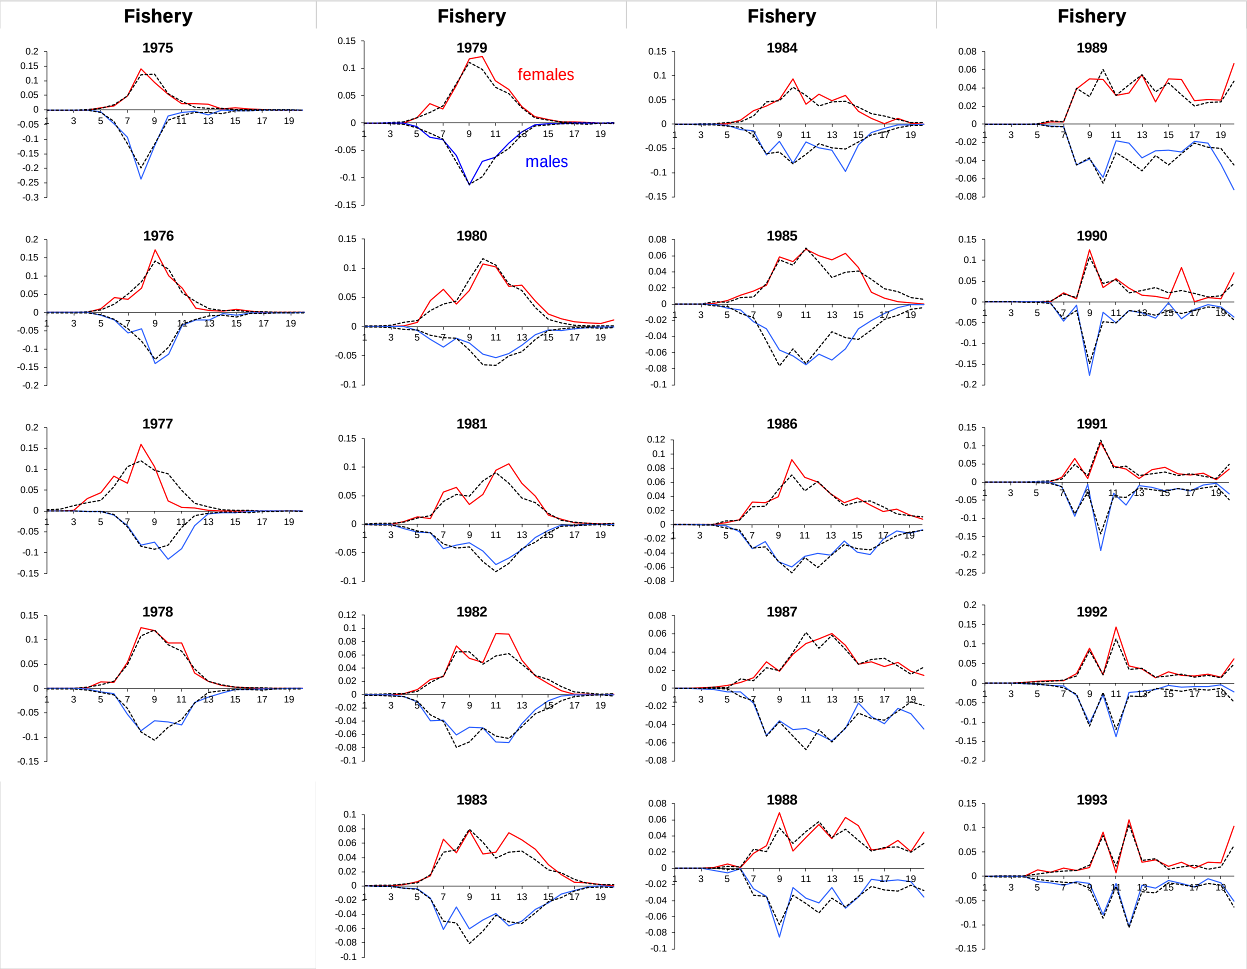

Figure 4.17. Stock assessment model fit to the time-series of fishery and survey age composition, by sex.

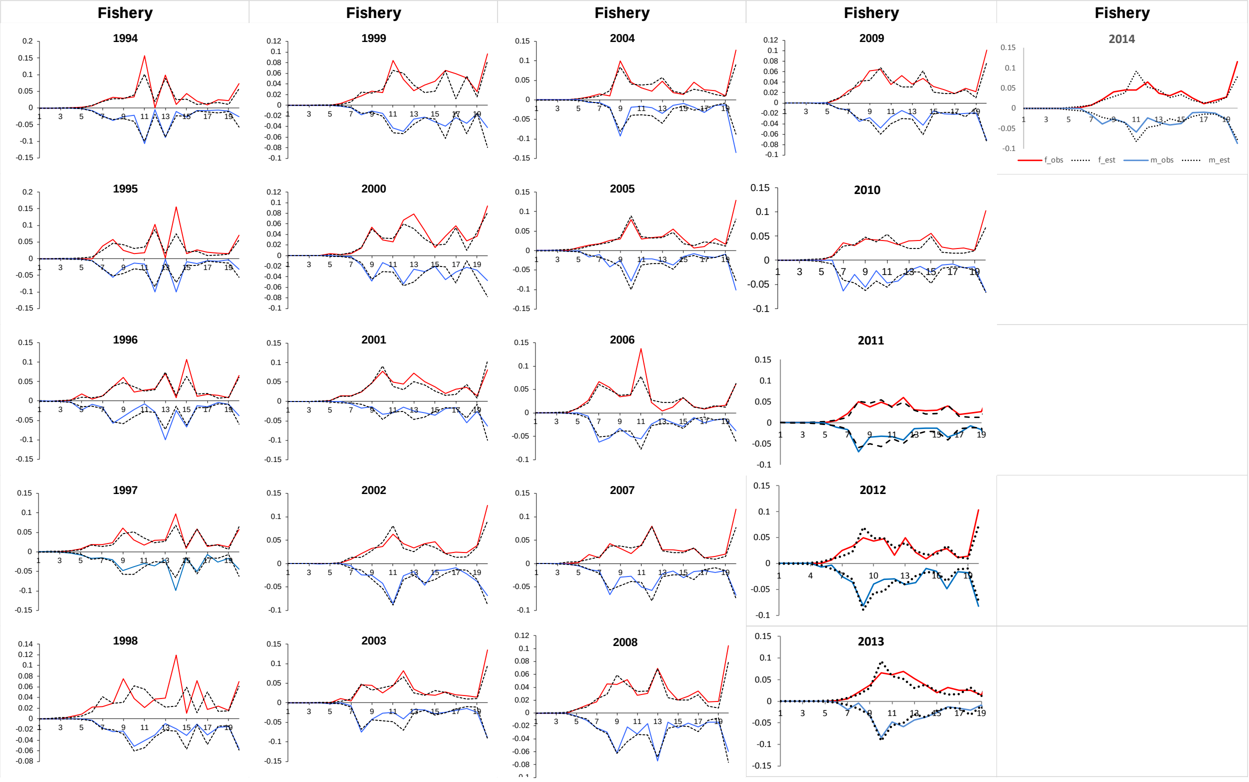

Figure 4.17 (continued).

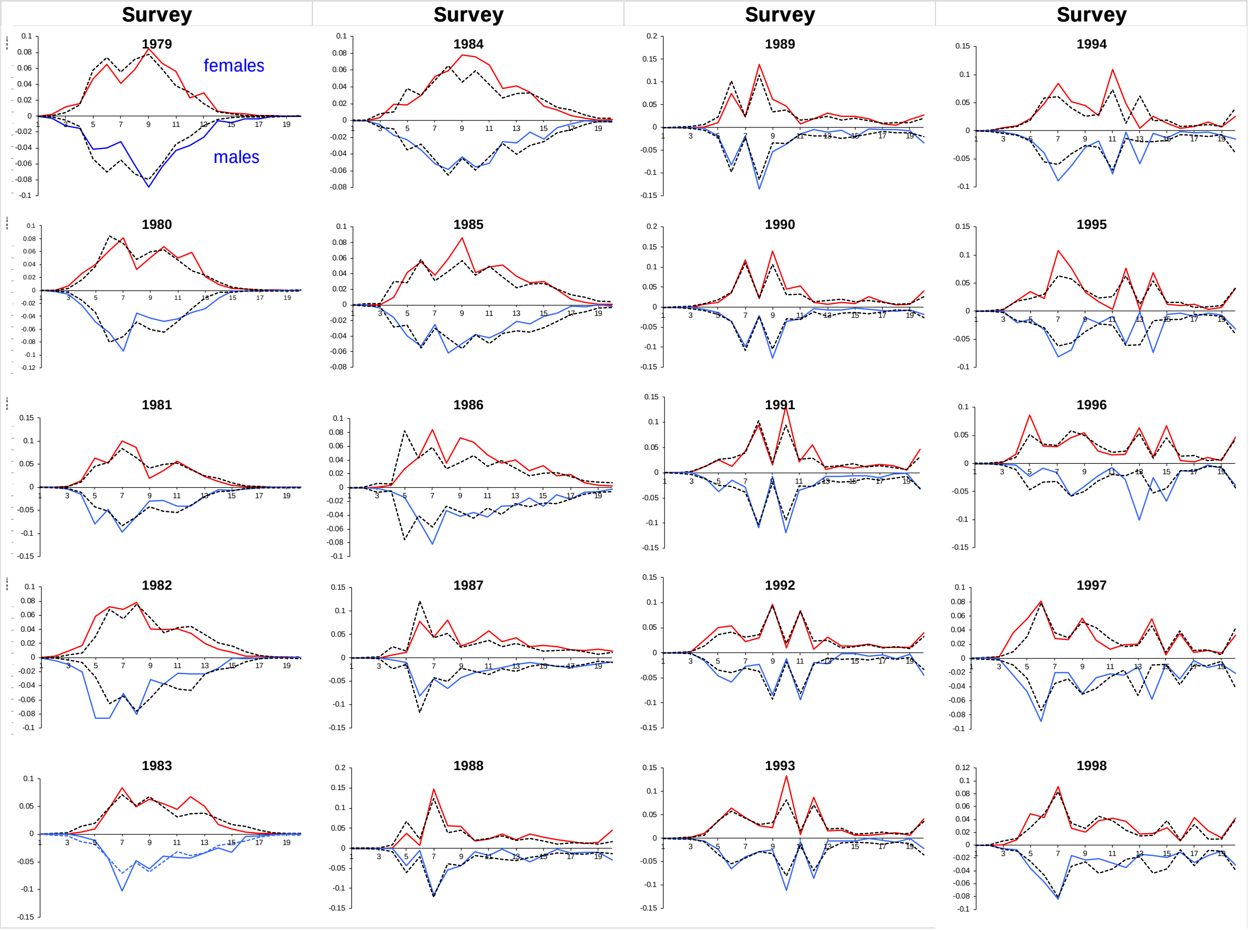

Figure 4.17 (continued).

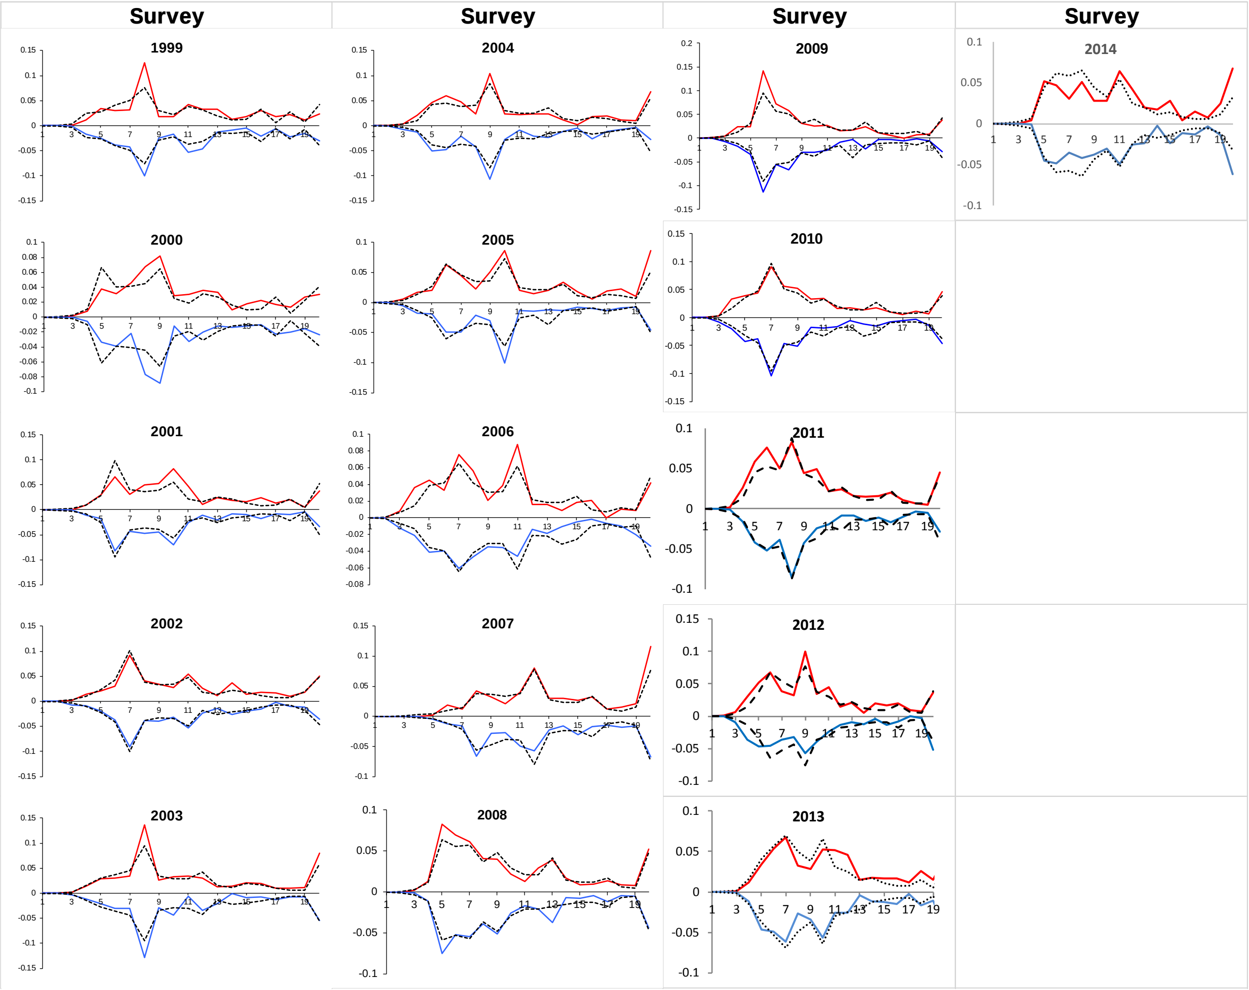

Figure 4.17 (continued).

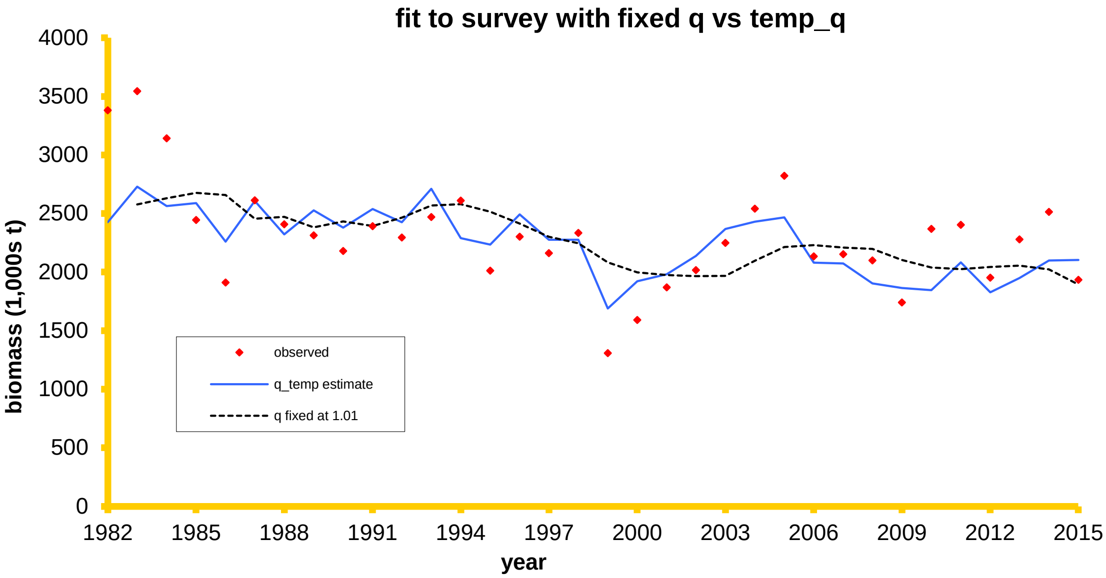

Figure 4.18.--Comparison of the fit to the survey biomass using a fixed q and the q-bottom temperature relationship.

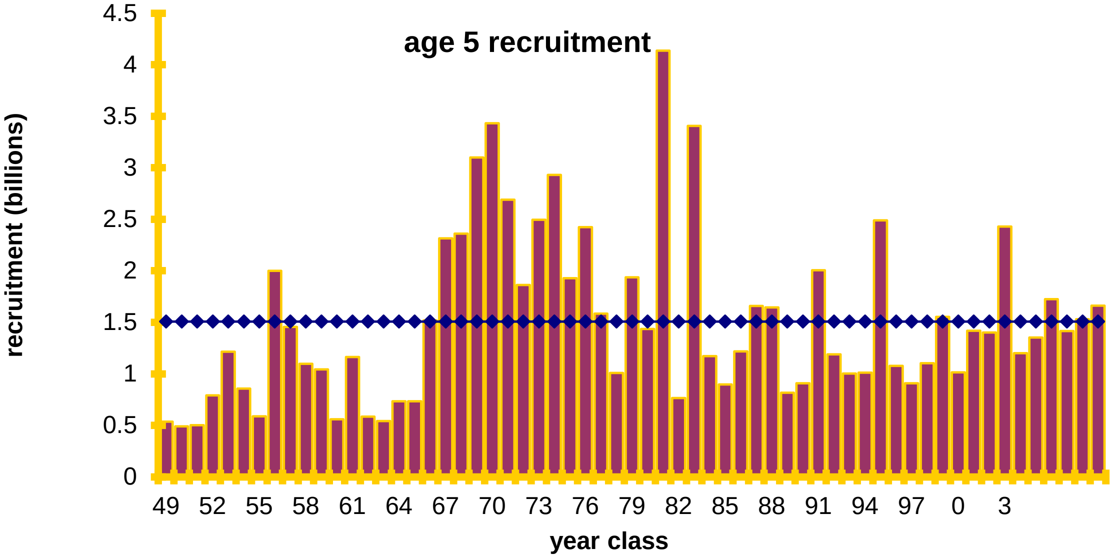

Figure 4.19--Year class strength of age 5 yellowfin sole estimated by the stock assessment model. The dotted line is the average of the estimates from 61 years of recruitment.

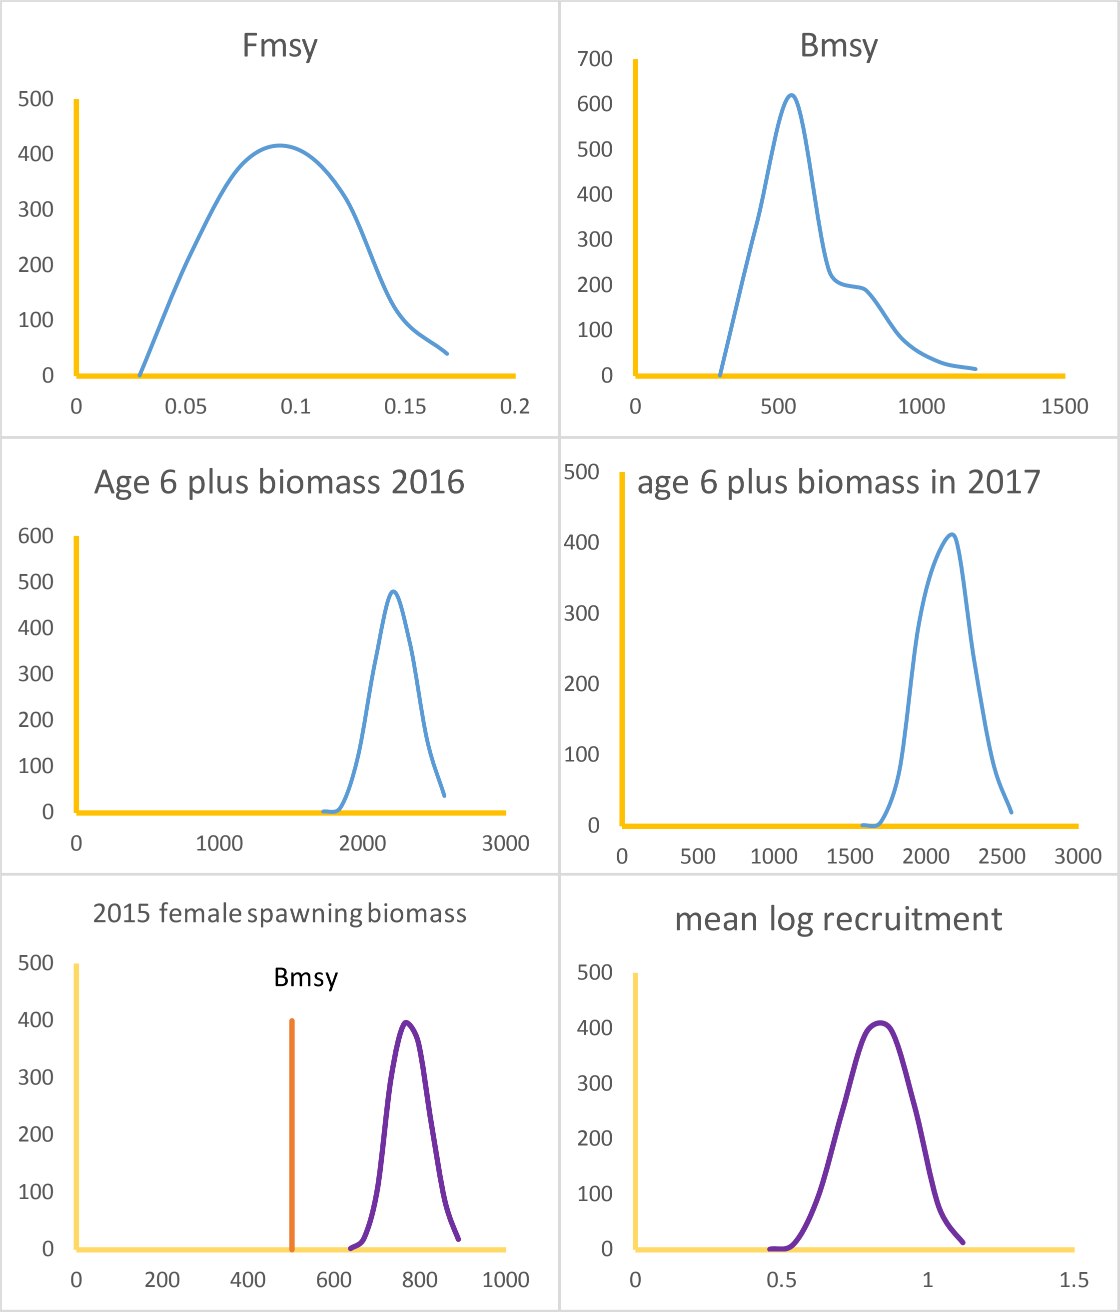

Figure 4.20.--Posterior distributions of some important parameters estimated by the preferred stock assessment model (from mcmc integration).

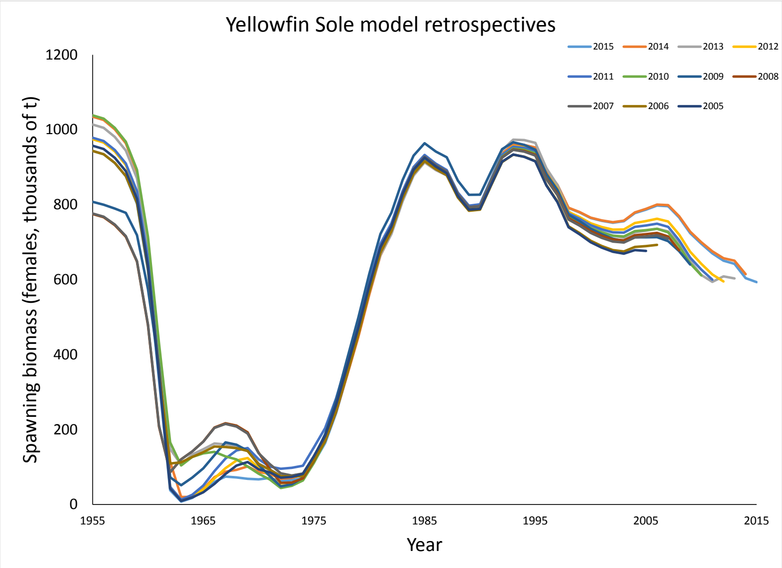

Figure 4.21—Retrospective plot of yellowfin sole female spawning biomass estimates (1,000s t), 2005-2015, from the recommended assessment model.

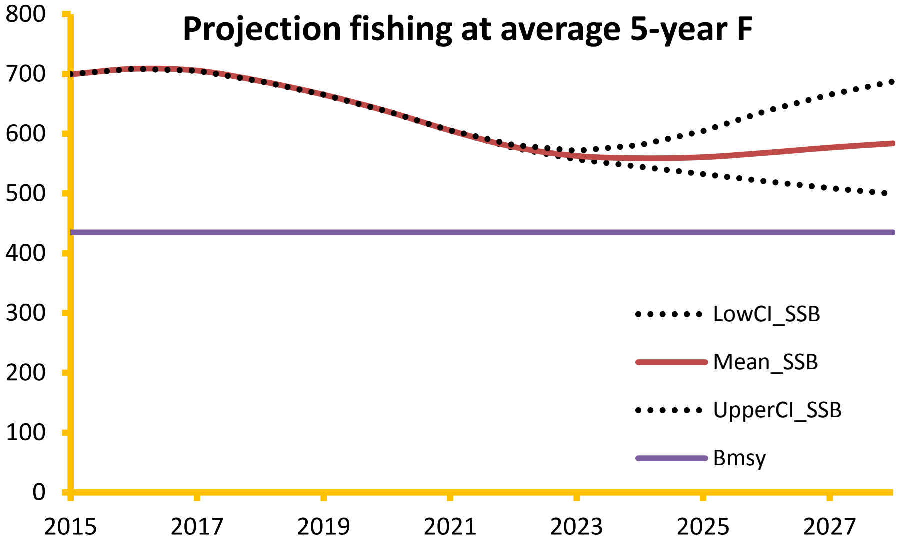

Figure 4.22.--Projection of yellowfin sole female spawning biomass (1,000s t) at the average full-selection F from the past 5 years (0.104) through 2028 with $B_{40\%}$ and B_{msy} levels indicated.

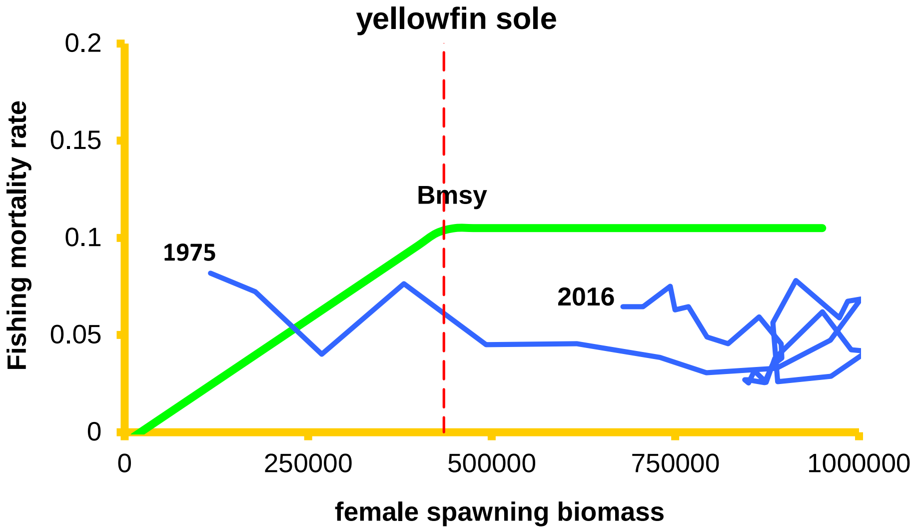

Figure 4.23.--Phase plane figure of the time-series of yellowfin sole female spawning biomass relative to the harvest control rule with 1975 and 2016 indicated.
