# 3. Assessment of the sablefish stock in Alaska 

by<br>Dana H. Hanselman, Chris R. Lunsford, and Cara J. Rodgveller

## Executive Summary

## Summary of changes in assessment inputs

Relative to last year's assessment, we made the following substantive changes in the current assessment.
Changes in the input data: New data included in the assessment model were relative abundance and length data from the 2015 longline survey, relative abundance and length data from the 2014 longline fishery, length data from the 2014 trawl fisheries, age data from the 2014 longline survey and 2014 fixed gear fishery, the 2015 Gulf of Alaska trawl survey abundance and length compositions, updated catch for 2014, and projected 2015-2017 catches.

Changes in the assessment methodology: There are no model changes.

| Summary of results |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
| Quantity/Status | As estimated or specified last year for: 2015 2016 |  | As estimated or recommended this year for: 2016* 2017* |  |
| $M$ (natural mortality rate) | 0.10 | 0.10 | 0.10 | 0.10 |
| Tier | 3b | 3b | 3 b | 3 b |
| Projected total (age 2+) biomass ( t ) | 219,997 | 227,042 | 204,796 | 214,552 |
| Projected female spawning biomass ( t ) | 91,183 | 88,345 | 86,471 | 81,986 |
| $B_{100 \%}$ | 262,269 | 262,269 | 257,018 | 257,018 |
| $B_{40 \%}$ | 104,908 | 104,908 | 102,807 | 102,807 |
| $B_{35 \%}$ | 91,794 | 91,794 | 89,956 | 89,956 |
| $F_{\text {OFL }}$ | 0.098 | 0.091 | 0.093 | 0.086 |
| $\operatorname{maxF}_{A B C}$ | 0.082 | 0.078 | 0.078 | 0.073 |
| $F_{A B C}$ | 0.082 | 0.078 | 0.078 | 0.073 |
| OFL (t) | 16,128 | 14,658 | 13,397 | 12,747 |
| $\max$ ABC (t) | 13,657 | 12,406 | 11,795 | 10,782 |
| $\mathrm{ABC}(\mathrm{t})$ | 13,657 | 12,406 | 11,795 | 10,782 |
| Status | As determined last year for: |  | As determined this year for: |  |
|  | 2013 | 2014 | 2014 | 2015 |
| Overfishing | No | n/a | No | n/a |
| Overfished | n/a | No | n/a | No |
| Approaching overfished | n/a | No | n/a | No |

* Projections are based on estimated catches of $9,781 \mathrm{t}$ and $8,715 \mathrm{t}$ used in place of maximum permissible ABC for 2016 and 2017. This was done in response to management requests for a more accurate two-year projection.

## Assessment results

The longline survey abundance index decreased $21 \%$ from 2014 to 2015 following a $15 \%$ increase from 2013 to 2014 and is at the lowest point of the time series. The fishery abundance index increased $6 \%$ from 2013 to 2014 (the 2015 data are not available yet). The Gulf of Alaska trawl survey index was at its lowest point in 2013 but increased 12\% in 2015. Spawning biomass is projected to decrease from 2016 to 2019, and then stabilize.

Sablefish are managed under Tier 3 of NPFMC harvest rules. Reference points are calculated using recruitments from 1977-2012. The updated point estimates of $B_{40 \%}, F_{40 \%}$ and $F_{35 \%}$ from this assessment are $102,807 \mathrm{t}$ (combined across the EBS, AI, and GOA), 0.094 , and 0.112 , respectively. Projected female spawning biomass (combined areas) for 2016 is $86,471 \mathrm{t}\left(84 \%\right.$ of $\left.B_{40 \%}\right)$, placing sablefish in sub-tier " b " of Tier 3. The maximum permissible value of $F_{A B C}$ under Tier 3 b is 0.078 , which translates into a 2016 ABC (combined areas) of $11,795 \mathrm{t}$. The OFL fishing mortality rate is 0.093 which translates into a 2016 OFL (combined areas) of $13,397 \mathrm{t}$. If the stock were in Tier 3a (above the $B_{40 \%}$ reference point), the 2016 ABC would be $14,164 \mathrm{t}$. Model projections indicate that this stock is not subject to overfishing, overfished, nor approaching an overfished condition.
We recommend a 2016 ABC of $\mathbf{1 1 , 7 9 5} \mathbf{t}$. The maximum permissible ABC for 2016 based on Tier 3b of the harvest control rule, uses an adjusted $F_{40 \%}$ which yields $11,795 \mathrm{t}$. The maximum permissible ABC for 2016 is $14 \%$ lower than the 2015 ABC of $13,657 \mathrm{t}$. The 2014 assessment projected a $10 \%$ decrease in ABC for 2016 from 2015. This slightly larger decrease is supported by a new low in the domestic longline survey index time series that offset the small increases in the fishery abundance index seen in 2014 and the Gulf of Alaska trawl survey index in 2015. The fishery abundance index has been trending down since 2007. The 2014 IPHC GOA sablefish index was not used in the model, but was similar and trending low in 2013 and 2014. The 2008 year class showed potential to be large in previous assessments based on patterns in the age and length compositions. However the estimate in this year's assessment is only just above average because the recent large overall decrease in the longline survey and trawl indices have lowered the overall scale of the population. Spawning biomass is projected to decline through 2018, and then is expected to increase assuming average recruitment is achieved in the future. ABCs are projected to decrease in 2017 to 10,782 t and 10,869 t in 2018 (see Table 3.18).

Projected 2016 spawning biomass is $\mathbf{3 4 \%}$ of unfished spawning biomass. Spawning biomass had increased from a low of $33 \%$ of unfished biomass in 2002 to $42 \%$ in 2008 and has now declined back to $34 \%$ of unfished biomass projected for 2016. The 1997 year class has been an important contributor to the population; however, it has been reduced and is predicted to comprise less than $6 \%$ of the 2016 spawning biomass. The last two above-average year classes, 2000 and 2008, each comprise $15 \%$ of the projected 2016 spawning biomass. The 2008 year class will be about $75 \%$ mature in 2016.

## Apportionment

In December 1999, the Council apportioned the 2000 ABC and OFL based on a 5 -year exponential weighting of the survey and fishery abundance indices. We have used the same algorithm to apportion the ABC and OFL since 2000. Following the standard apportionment scheme, we have observed that the objective to reduce variability in apportionment was not being achieved. Since 2007, the mean change in apportionment by area has increased annually (Figure 3.36A). While some of these changes may actually reflect interannual changes in regional abundance, they most likely reflect the high movement rates of the population and the high variability of our estimates of abundance in the Bering Sea and Aleutian Islands. For example, the apportionment for the Bering Sea has varied drastically since 2007, attributable to high variability in both survey abundance and fishery CPUE estimates in the Bering Sea (Figure 3.36B). These large annual changes in apportionment result in increased variability of ABCs by area, including areas other than the Bering Sea (Figure 3.36C). Because of the high variability in apportionment seen in recent years, we do not believe the standard method is meeting the goal of reducing the magnitude of interannual changes in the apportionment. Because of these reasons, we recommended fixing the apportionment at the proportions from the 2013 assessment, until the apportionment scheme is thoroughly reevaluated and reviewed. A Ph.D. student with the University of Alaska-Fairbanks began a project in 2013 with the objectives of re-examining the apportionment strategy and conducting a management strategy evaluation. A spatial sablefish model has been developed, but the management strategy evaluation is in early stages of development. Meanwhile, it seems imprudent to move to an interim apportionment or return to the former scheme until more satisfactory methods have been identified and evaluated. Therefore, for 2016, we recommend continuing with the apportionment fixed at the proportions used in 2015.

| Area | 2015 ABC | Standard apportionment for 2016 ABC | Recommended fixed apportionment for 2016 ABC* | Difference from 2015 |
| :---: | :---: | :---: | :---: | :---: |
| Total | 13,657 | 11,795 | 11,795 | -13.6\% |
| Bering Sea | 1,333 | 1,816 | 1,151 | -13.6\% |
| Aleutians | 1,802 | 1,627 | 1,557 | -13.6\% |
| Gulf of Alaska (subtotal) | 10,522 | 8,352 | 9,087 | -13.6\% |
| Western | 1,473 | 1,136 | 1,272 | -13.6\% |
| Central | 4,658 | 3,451 | 4,023 | -13.6\% |

## Responses to SSC and Plan Team Comments on Assessments in General

"The SSC requests that stock assessment authors utilize the following model naming conventions in SAFE chapters:

Model 0: last years' model with no new data,
Model 1: last years' model with updated data, and
Model numbers higher than 1 are for proposed new models.": SSC, December 2014
"For this year's final assessments, the Teams recommend that each author of an age-structured assessment use one of the following model naming conventions ("TPA" represents the alternative described in the Team procedures document)...": Joint Plan Team, September, 2015
"Of the options presented in the Joint Plan Teams minutes, the SSC agrees that that Option 4 has several advantages and recommends that this Option be advanced next year.": SSC, October 2015

For this assessment, we will use the simplified convention suggested in the December SSC minutes and will investigate further detailed naming for the next assessment cycle in 2016.

The SSC also requests that stock assessment authors utilize the random effects model for area apportionment of ABCs": SSC, December 2014
"The Teams recommend that the random effects survey smoothing model be used as a default for determining current survey biomass and apportionment among areas.": Joint Plan Teams, September 2015

The sablefish model has used a 5 year exponential smoothing model of fishery and survey CPUE developed at the Council level that was based on the univariate Kalman filter model. This is similar to the random effects apportionment model, which smooths biomass by balancing process and measurement error. We will examine the random effects apportionment model in the future as different apportionment options are being examined for sablefish.

## Responses to SSC and Plan Team Comments Specific to this Assessment

There were no recommendations specific to sablefish in 2014 or 2015.

## Introduction

## Distribution

Sablefish (Anoplopoma fimbria) inhabit the northeastern Pacific Ocean from northern Mexico to the Gulf of Alaska (GOA), westward to the Aleutian Islands (AI), and into the Bering Sea (BS) (Wolotira et al. 1993). Adult sablefish occur along the continental slope, shelf gullies, and in deep fjords, generally at depths greater than 200 m . Sablefish observed from a manned submersible were found on or within 1 m of the bottom (Krieger 1997). In contrast to the adult distribution, juvenile sablefish spend their first two to three years on the continental shelf of the GOA, and occasionally on the shelf of the southeast BS. The BS shelf is utilized significantly in some years and seldom used during other years (Shotwell et al. 2012).

## Early life history

Spawning is pelagic at depths of $300-500 \mathrm{~m}$ near the edges of the continental slope (Mason et al. 1983, McFarlane and Nagata 1988), with eggs developing at depth and larvae developing near the surface as far offshore as 180 miles (Wing 1997). Along the Canadian coast (Mason et al. 1983) and off Southeast Alaska (Jennifer Stahl, February, 2010, ADF\&G, pers. comm.) sablefish spawn from January-April with a peak in February. In a survey near Kodiak Island in December, 2011 that targeted sablefish preparing to spawn, spawning appeared to be imminent, but spent fish were not found. It is likely that they would spawn in January or February (Katy Echave, October 2012, AFSC, pers. comm.). Farther down the coast off of central California sablefish spawn earlier, from October-February (Hunter et al. 1989). An analysis of larval otoliths showed that spawning in the Gulf of Alaska may be a month later than southern sablefish (Sigler et al. 2001). Sablefish in spawning condition were also noted as far west as Kamchatka in November and December (Orlov and Biryukov 2005). Larval sablefish sampled by neuston net in the eastern Bering Sea fed primarily on copepod nauplii and adult copepods (Grover and Olla 1990). In gill nets set at night for several years on the AFSC longline survey, most young-of-the-year sablefish were caught in the central and eastern GOA (Sigler et al. 2001). Near the end of the first summer, pelagic juveniles less than 20 cm move inshore and spend the winter and following summer in inshore waters where they exhibit rapid growth, reaching $30-40 \mathrm{~cm}$ by the end of their second summer (Rutecki and Varosi 1997). Gao et al. (2004) studied stable isotopes in otoliths of juvenile sablefish from Oregon and Washington and found that as the fish increased in size they shifted from midwater prey to more benthic prey. In nearshore southeast Alaska, juvenile sablefish ( $20-45 \mathrm{~cm}$ ) diets included fish such as Pacific herring and smelts and invertebrates such as krill, amphipods and polychaete worms (Coutré et al. 2015). In late summer, juvenile sablefish also consumed post-spawning pacific salmon carcass remnants in high volume revealing opportunistic scavenging (Coutré et al. 2015). After their second summer, they begin moving offshore to deeper water, typically reaching their adult habitat, the upper continental slope at 4 to 5 years. This corresponds to the age range when sablefish start becoming reproductively viable (Mason et al. 1983).

## Movement

A movement model for Alaskan sablefish was developed for Alaskan sablefish by Heifetz and Fujioka (1991) based on 10 years of tagging data. The model has been updated by incorporating data from 19792009 in an AD Model Builder program, with time-varying reporting rates, and tag recovery data from ADF\&G for State inside waters (Southern Southeast Inside and Northern Southeast Inside). In addition, the study estimated mortality rates from the tagging data (Hanselman et al. 2015). Annual movement probabilities were high, ranging from $10-88 \%$ depending on area of occupancy at each time step, and size group. Overall, movement probabilities were very different between areas of occupancy and moderately different between size groups. Estimated annual movement of small sablefish from the central Gulf of Alaska had the reverse pattern of a previous study, with $29 \%$ moving westward and $39 \%$ moving
eastward. Movement probabilities also varied annually with decreasing movement until the late 1990s and increasing movement until 2009. Year specific magnitude in movement probability of large fish was highly negatively correlated with female spawning biomass estimates from the federal stock assessment (i.e., when spawning biomass is high, they move less). Average mortality estimates from time at liberty were similar to the stock assessment.

## Stock structure

Sablefish have traditionally been thought to form two populations based on differences in growth rate, size at maturity, and tagging studies (McDevitt 1990, Saunders et al. 1996, Kimura et al. 1998). The northern population inhabits Alaska and northern British Columbia waters and the southern population inhabits southern British Columbia, Washington, Oregon, and California waters, with mixing of the two populations occurring off southwest Vancouver Island and northwest Washington. Significant stock structure among the federal Alaska population is unlikely given extremely high movement rates throughout their lives (Hanselman et al. 2015, Heifetz and Fujioka 1991, Maloney and Heifetz 1997, Kimura et al. 1998).

## Fishery

## Early U.S. fishery, 1957 and earlier

Sablefish have been exploited since the end of the $19^{\text {th }}$ century by U.S. and Canadian fishermen. The North American fishery on sablefish developed as a secondary activity of the halibut fishery of the United States and Canada. Initial fishing grounds were off Washington and British Columbia and then spread to Oregon, California, and Alaska during the 1920's. Until 1957, the sablefish fishery was exclusively a U.S. and Canadian fishery, ranging from off northern California northward to Kodiak Island in the GOA; catches were relatively small, averaging 1,666 t from 1930 to 1957, and generally limited to areas near fishing ports (Low et al. 1976).

## Foreign fisheries, 1958 to 1987

Japanese longliners began operations in the eastern BS in 1958. The fishery expanded rapidly in this area and catches peaked at $25,989 \mathrm{t}$ in 1962 (Table 3.1, Figures 3.1, 3.2). As the fishing grounds in the eastern Bering were preempted by expanding Japanese trawl fisheries, the Japanese longline fleet expanded to the AI region and the GOA. In the GOA, sablefish catches increased rapidly as the Japanese longline fishery expanded, peaking at $36,776 \mathrm{t}$ overall in 1972. Catches in the AI region remained at low levels with Japan harvesting the largest portion of the sablefish catch. Most sablefish harvests were taken from the eastern Being Sea until 1968, and then from the GOA until 1977. Heavy fishing by foreign vessels during the 1970's led to a substantial population decline and fishery regulations in Alaska, which sharply reduced catches. Catch in the late 1970's was restricted to about one-fifth of the peak catch in 1972, due to the passage of the Fishery Conservation and Management Act (FCMA).
Japanese trawlers caught sablefish mostly as bycatch in fisheries targeting other species. In the BS, the trawlers were mainly targeting rockfishes, Greenland turbot, and Pacific cod, and only a few vessels targeted sablefish. In the GOA, sablefish were mainly caught as bycatch in the directed Pacific Ocean perch fishery until 1972, when some vessels started targeting sablefish in 1972 (Sasaki 1985).
Other foreign nations besides Japan also caught sablefish. Substantial Soviet Union catches were reported from 1967-73 in the BS (McDevitt 1986). Substantial Korean catches were reported from 1974-1983 scattered throughout Alaska. Other countries reporting minor sablefish catches were Republic of Poland, Taiwan, Mexico, Bulgaria, Federal Republic of Germany, and Portugal. The Soviet gear was factory-type stern trawl and the Korean gears were longlines and pots (Low et al. 1976).

## Recent U.S. fishery, 1977 to present

The U.S. longline fishery began expanding in 1982 in the GOA, and by 1988, the U.S. harvested all sablefish taken in Alaska, except minor joint venture catches. Following domestication of the fishery, the previously year-round season in the GOA began to shorten in 1984 from 12 months in 1983 to 10 days in 1994, warranting the label "derby" fishery.
In 1995, Individual Fishery Quotas (IFQ) were implemented for hook-and-line vessels along with an 8month season. The IFQ Program is a catch share fishery that issued quota shares to individuals based on sablefish and halibut landings made from 1988-1990. Since the implementation of IFQ's, the number of longline vessels with sablefish IFQ harvests has experienced a substantial anticipated decline from 616 in 1995 to 362 in 2011 (NOAA 2012). This decrease was expected as shareholders have consolidated their holdings and fish them off fewer vessels to reduce costs (Fina 2011). The sablefish fishery has historically been a small boat fishery; the median vessel length in the 2011 fishery was 56 ft . In recent years, approximately $30 \%$ of vessels eligible to fish in the IFQ fishery participate in both the halibut and sablefish fisheries and approximately $40 \%$ of vessels fish in more than one management area. The season dates have varied by several weeks since 1995, but the monthly pattern has been from March to November with the majority of landings occurring in May - June. The number of landings fluctuates with quota size, but in 2011 there were 1,726 landings recorded in the Alaska fishery (NOAA 2012).

Pot fishing in the IFQ fishery is not allowed in the GOA but is legal in the BSAI regions. In 2000, the pot fishery accounted for less than ten percent of the fixed gear sablefish catch in these areas but effort has increased substantially in response to killer whale depredation. Pots are longlined with approximately 40135 pots per set. Since 2004, pot gear has accounted for over $50 \%$ of the BS fixed gear IFQ catch and up to $34 \%$ of the fixed gear catch in the AI.

Sablefish also are caught incidentally during directed trawl fisheries for other species groups such as rockfish and deepwater flatfish. Allocation of the TAC by gear group varies by management region and influences the amount of catch in each region (Table 3.1, Figures 3.1, 3.2). Five State of Alaska fisheries land sablefish outside the IFQ program; the major State fisheries occur in the Prince William Sound, Chatham Strait, and Clarence Strait and the minor fisheries in the northern GOA and AI. The minor state fisheries were established by the State of Alaska in 1995, the same time as the Federal Government established the IFQ fishery, primarily to provide open-access fisheries to fishermen who could not participate in the IFQ fishery.
IFQ management has increased fishery catch rates and decreased the harvest of immature fish (Sigler and Lunsford 2001). Catching efficiency (the average catch rate per hook for sablefish) increased 1.8 times with the change from an open-access to an IFQ fishery. The change to IFQ also decreased harvest and discard of immature fish which improved the chance that these fish will reproduce at least once. Thus, the stock can provide a greater yield under IFQ at the same target fishing rate because of the selection of older fish (Sigler and Lunsford 2001).
Longline gear in Alaska is fished on-bottom. Since the inception of the IFQ system, average set length in the directed fishery for sablefish has been near 9 km and average hook spacing near 1.2 m . The gear is baited by hand or by machine, with smaller boats generally baiting by hand and larger boats generally baiting by machine. Circle hooks are usually used, except for modified J-hooks on some boats with machine baiters. The gear usually is deployed from the vessel stern with the vessel traveling at 5-7 knots. Some vessels attach weights to the longline, especially on rough or steep bottom, so that the longline stays in place on bottom.

## Management measures/units

A summary of historical catch and management measures pertinent to sablefish in Alaska are shown in Table 3.7. Influential management actions regarding sablefish include:

## Management units

Sablefish are assessed as a single population in Federal waters off Alaska because of their high movement rates. Sablefish are managed by discrete regions to distribute exploitation throughout their wide geographical range. There are four management areas in the GOA: Western, Central, West Yakutat, and East Yakutat/Southeast Outside; and two management areas in the Bering Sea/Aleutian Islands (BSAI): the BS and the AI regions. Amendment 8 to the GOA Fishery Management Plan established the West and East Yakutat management areas for sablefish, effective 1980.

## Quota allocation

Amendment 14 to the GOA Fishery Management Plan allocated the sablefish quota by gear type: $80 \%$ to fixed gear (including pots) and 20\% to trawl in the Western and Central GOA, and $95 \%$ to fixed gear and $5 \%$ to trawl in the Eastern GOA, effective 1985. Amendment 15 to the BS/AI Fishery Management Plan, allocated the sablefish quota by gear type, $50 \%$ to fixed gear and $50 \%$ to trawl in the eastern BS, and $75 \%$ to fixed gear and $25 \%$ to trawl gear in the Aleutians, effective 1990.

## IFQ management

Amendment 20 to the GOA Fishery Management Plan and 15 to the BS/AI Fishery Management Plan established IFQ management for sablefish beginning in 1995. These amendments also allocated $20 \%$ of the fixed gear allocation of sablefish to a CDQ reserve for the BS and AI.

## Maximum retainable allowances

Maximum retainable allowances for sablefish as the "incidental catch species" were revised in the GOA by a regulatory amendment, effective April, 1997. The percentage depends on the basis species: $1 \%$ for pollock, Pacific cod, Atka mackerel, "other species", and aggregated amount of non-groundfish species. Fisheries targeting deep flatfish, rex sole, flathead sole, shallow flatfish, Pacific ocean perch, northern rockfish, dusky rockfish, and demersal shelf rockfish in the Southeast Outside district, and thornyheads are allowed $7 \%$. The MRA for arrowtooth flounder changed effective 2009 in the GOA, to $1 \%$ for sablefish as the basis species.

## Allowable gear

Amendment 14 to the GOA Fishery Management Plan banned the use of pots for fishing for sablefish in the GOA, effective 18 November 1985, starting in the Eastern area in 1986, in the Central area in 1987, and in the Western area in 1989. An earlier regulatory amendment was approved in 1985 for 3 months ( 27 March - 25 June 1985) until Amendment 14 was effective. A later regulatory amendment in 1992 prohibited longline pot gear in the BS ( 57 FR 37906). The prohibition on sablefish longline pot gear use was removed for the BS, except from 1 to 30 June to prevent gear conflicts with trawlers during that month, effective 12 September 1996. Sablefish longline pot gear is allowed in the AI. In April of 2015 the NPFMC passed a motion to again allow for sablefish pot fishing in the GOA in response to increased sperm whale depredation. The final motion was passed and the new regulations are expected in early 2016. We will carefully monitor the development of this gear type in the Gulf of Alaska.

## Catch

Annual catches in Alaska averaged about 1,700 t from 1930 to 1957 and exploitation rates remained low until Japanese vessels began fishing for sablefish in the BS in 1958 and the GOA in 1963. Catches rapidly escalated during the mid-1960s. Annual catches in Alaska reached peaks in 1962, 1972, and 1988 (Table 3.1, Figure 3.2). The 1972 catch was the all-time high, at $53,080 \mathrm{t}$, and the 1962 and 1988 catches were $50 \%$ and $72 \%$ of the 1972 catch. Evidence of declining stock abundance and passage of the MSFCMA led to significant fishery restrictions from 1978 to 1985, and total catches were reduced substantially.
Exceptional recruitment fueled increased abundance and increased catches during the late 1980's, which coincided with the domestic fishery expansion. Catches declined during the 1990's, increased in the early

2000s, and have since declined to near 12,000 $t$ (Figure 3.1). TACs in the GOA are nearly fully utilized, while TACs in the BS and AI are rarely fully utilized.

## Bycatch and discards

Sablefish discards by target fisheries are available for hook-and-line gear and other gear combined (Table 3.3). From 1994 to 2004 discards averaged $1,357 \mathrm{t}$ for the GOA and BSAI combined (Hanselman et al. 2008). Since then, discards have been lower, averaging 608 t between 2007 and 2014. Discard rates are generally higher in the GOA than in the BSAI (Table 3.3).

Table 3.4 shows the average bycatch of Fishery Management Plans' (FMP) groundfish species in the sablefish target fishery from 2009-2015. The largest bycatch group is GOA thornyhead rockfish ( 575 t /year, 174 t discarded). Sharks and skates are also taken in substantial numbers and are mostly discarded.

Giant grenadiers, a non-target species that is soon entering both FMPs as an Ecosystem Component, make up the bulk of the nontarget species bycatch, with 2013 the highest in the last five years at 7,929 t (Table 3.5). Other nontarget taxa that have catches over one ton per year are corals, snails, sponges, sea stars, and miscellaneous fishes and crabs.

Prohibited species catches (PSC) in the targeted sablefish fisheries are dominated by halibut ( $334 \mathrm{t} / \mathrm{year}$ on average) and golden king crab (47,000 individuals/year on average) (Table 3.6). Crab catches are highly variable from year to year, probably as a result of relatively low observer sampling effort in sablefish fisheries.

## Data

The following table summarizes the data used for this assessment:

| Source | Data | Years |
| :--- | :--- | :--- |
| Fixed gear fisheries | Catch | $1960-2015$ |
| Trawl fisheries | Catch | $1960-2015$ |
| Japanese longline fishery | Catch-per-unit-effort (CPUE) | $1964-1981$ |
| U.S. fixed gear fishery | CPUE, length | $1990-2014$ |
|  | Age | $1999-2014$ |
| U.S. trawl fisheries | Length | $1990,1991,1999,2005-2014$ |
| Japan-U.S. cooperative longline | CPUE, length | $1979-1994$ |
| survey |  |  |
|  | Age | $1981,1983,1985,1987,1989,1991$, |
| Domestic longline survey | CPUE, length | 1993 |
|  | Age | $1990-2015$ |
| NMFS GOA trawl survey | Abundance index | $1996-2014,1987,1990,1993,1996,1999$, |
|  |  | $2003,2005,2007,2009,2011,2013$, |
|  | Lengths | $1984,1987,1990,1993,1996,1999$, |
|  |  | $2003,2005,2007,2009,2011,2013$ |

## Fishery

Length, catch, and effort data were historically collected from the Japanese and U.S. longline and trawl fisheries, and are now collected from U.S. longline, trawl, and pot fisheries (Table 3.8). The Japanese data were collected by fishermen trained by Japanese scientists (L. L. Low, August 25, 1999, AFSC, pers. comm.). The U.S. fishery length and age data were collected by at-sea and plant observers. No age data were collected from the fisheries until 1999 because of the difficulty of obtaining representative samples from the fishery and because only a small number of sablefish can be aged each year.

## Catch

The catches used in this assessment (Table 3.1) include catches from minor State-managed fisheries in the northern GOA and in the AI region because fish caught in these State waters are reported using the area code of the adjacent Federal waters in the Alaska Regional Office catch reporting system (G. Tromble, July 12, 1999, Alaska Regional Office, pers. comm.), the source of the catch data used in this assessment. Minor State fisheries catches averaged 180 t from 1995-1998, about $1 \%$ of the average total catch. Most of the catch $(80 \%)$ is from the AI region. The effect of including these State waters catches in the assessment is to overestimate biomass by about $1 \%$, a negligible error considering statistical variation in other data used in this assessment. Catches from state areas that conduct their own assessments and set Guideline Harvest levels (e.g., Prince William Sound, Chatham Strait, and Clarence Strait), are not included in this assessment.
Some catches probably were not reported during the late 1980's (Kinoshita et al. 1995). Unreported catches could account for the Japan-U.S. cooperative longline survey index's sharp drop from 1989-90 (Table 3.8, Figures 3.3). We tried to estimate the amount of unreported catches by comparing reported catch to another measure of sablefish catch, sablefish imports to Japan, the primary buyer of sablefish. However the trends of reported catch and imports were similar, so we decided to change our approach for catch reporting in the 1999 assessment (Sigler et al. 1999). We assumed that non-reporting is due to at-sea discards, and apply discard estimates from 1994 to 1997 to inflate U.S. reported catches in all years prior to 1993 ( $2.9 \%$ for hook-and-line and $26.6 \%$ for trawl).
In response to Annual Catch Limit (ACL) requirements, assessments now document all removals including catch that are not associated with a directed fishery. Research catches of sablefish have been reported in previous stock assessments (Hanselman et al. 2009). Estimates of all removals not associated with a directed fishery including research catches are available and are presented in Appendix 3B. The sablefish research removals are small relative to the fishery catch, but substantial compared to the research removals for many other species. These research removals support a dedicated longline survey. Additional sources of significant removals are bottom trawl surveys and the International Pacific Halibut Commission's longline survey. Other removals are relatively minor for sablefish but the sport fishery catch has been increasing in recent years, but occurs primarily in State waters. Total removals from activities other than directed fishery have been between 239-359 t since 2006. These catches are not included in the stock assessment model. These removal estimates equate to approximately $2 \%$ of the recommended ABC and represent a relatively low risk to the sablefish stock.

## Lengths

We use length compositions from the U.S. fixed gear (longline and pot) and U.S. trawl fisheries which are both measured by sex. The fixed gear fishery has large sample sizes and has annual data since 1990. The trawl fishery had low levels of observer sampling in much of the 1990s and early 2000s, and has a much smaller sample size than the fixed gear fishery. We only use years for the trawl fishery that have sample sizes of at least 300 per sex. The length compositions are weighted by catch in each FMP management area to obtain a representative estimate of catch-at-length.

## Ages

We use age compositions from the U.S. fixed gear fishery since 1999. Sample sizes are similar to the longline survey with about 1,200 otoliths aged every year. The age compositions are weighted by the catch in each area to obtain a representative estimate of catch-at-age.

## Longline fishery catch rate index

Fishery information is available from longline sets that target sablefish in the IFQ fishery. Records of catch and effort for these vessels are collected by observers and by vessel captains in voluntary and required logbooks. Fishery data from the Observer Program is available since 1990. Logbooks are required for vessels over 60 feet beginning in 1999. Since 2000, a longline fishery catch rate index has
been derived from observed sets and logbook data for use in the model and in apportionment. The mean CPUE is scaled to a relative population weight by the total area size in each area. In the years that logbook and observer CPUEs are available, the average of the two sources is computed by weighting with the inverse of the coefficient of variation.

## Targeted sablefish longline sample sizes

For analysis of observed sablefish catch rates in the sablefish target fishery, we first have to determine the target of the set, because the target is not declared in the observer data set. To do this, we compare the catch of sablefish to other target species that are typically caught on longline gear: Greenland turbot, several rockfish species, Pacific halibut, and Pacific cod. Whichever target fishery has the greatest weight in the set is regarded as the target Catch rates and sample sizes presented here only include sets where sablefish were determined to be the target. The total weight of all sets recorded by observers determined to be targeting sablefish represent on average $14 \%$ of the annual IFQ hook and line catch. In 2014 they comprised $12 \%$ of the hook and line catch ( $1,407 \mathrm{mt}$ ). On average, the percent of the IFQ catch observed is lowest in the EY/SE (5\%), highest in WY and $\mathrm{AI}(\sim 22 \%)$, and moderate in the BS, CGOA, and WGOA (10-14\%). In $201420 \%$ of catch in the AI catch was observed, $4 \%$ in the BS, $9 \%$ in the WG, $15 \%$ in the CG, $18 \%$ in WY, and $10 \%$ in EY/SE. In 2014, coverage in EY/SE was higher than average and lower than average in the BS and WY areas. This may partially be due to observer restructuring, where more coverage was directed to smaller vessels, which are more common in EY/SE. Low longline fishery sample sizes in the BS are also likely a result of poor observer coverage for sablefish directed trips and an increase in pot fishing in the BS (Table 3.9). Because of confidentiality concerns, the catch rates with less than three vessels cannot be shown.
Killer whales impact sablefish catch rates in the BS, AI and WGOA and these sets are excluded from catch rate analyses in the observer data set. Whale data is not currently collected in logbooks. Since 2009, there has been an increase in killer whale depredation in the WGOA (average $6 \%$ from 2010-2013); however, this is only 7-22 sets per year. In the AI and BS, killer whale depredation has been variable, ranging from 0-12 sets per year in each area. In 2014 there was sperm whale depredation on 10 sets in the CGOA ( $1.7 \%$ of sets). Sperm whale depredation typically occurs in the CGOA, EY/SE, and WY. In $20147 \%$ of sets in the CG and EY were depredated and $20 \%$ in the WY. In 2014 there were a few sets with sperm whale depredation in the AI ( 6 sets) and in the WGOA ( 5 sets). The percent of sets affected by sperm whales varies greatly and determining if sperm whales are depredating can be subjective because whales do not take the great majority of the catch, like killer whales do. Therefore, measures of depredation in the fishery may not be accurate.
Logbook sample sizes are substantially higher than observer samples sizes, especially since 2004, and have continued to rise annually in many management areas (WGOA, WY, CGOA) (Table 3.9). Logbook participation increased sharply in 2004 in all areas primarily because the International Pacific Halibut Commission (IPHC) was used to collect, edit, and enter logbooks electronically. This increasing trend is likely due to the strong working relationship the IPHC has with fishermen, their diligence in collecting logbooks dockside, and because many vessels $<60$ feet are now participating in the program voluntarily. In $201468 \%$ of the logs collected that targeted sablefish were from vessels $<60 \mathrm{ft}$. There is a higher proportion of the catch documented by logbooks than by observers; $50 \%$ of the hook and line catch was documented in logbooks, compared to $12 \%$ for observer data. Some data is included in both data sets if logbooks are required and an observer was onboard.

## Longline catch rates

Sets where there was killer whale depredation are excluded for catch rate calculations in observer data, but whale depredation is not documented in logbooks and so no data are excluded. In general, catch rates are highest in the EY/SE and WY areas and are lowest in the BS and AI (Table 3.9, Figures 3.5 and 3.6). Recently, catch rate trends in the observer and logbook data have been similar in all areas except WY, where observer data shows a sharp decrease in $2014(25 \%)$ and logbooks show only a $1 \%$ decrease. Catch
rates from logbooks were stable or slightly up in all areas while the sparser observer data were a little more variable.

## Longline spatial and temporal patterns

Changes in spatial or temporal patterns of the fishery may cause fishery catch rates to be unrepresentative of abundance. For example, fishers sometimes target concentrations of fish, even as geographic distribution shrinks when abundance declines (Crecco and Overholtz 1990). This could lead to an incorrect interpretation of fishery catch rates, which could remain stable while the area occupied by the stock was diminishing (Rose and Kulka 1999).
We examined fishery longline data for seasonal and annual differences in effort and catch rate (CPUE, $\mathrm{lbs} /$ hook). Such changes may cause fishery catch rates to be unrepresentative of abundance. In the observed longline data since 2000, the majority of effort occurs in the spring, less in the summer, and least in the fall. Since 1998, catch rates are also highest in the spring, moderate in the summer, and variable in the fall (due to lower sample sizes in the fall). No temporal changes have emerged in the logbook or observer data.

## Seasonal changes in fish size

From 2012-2014 there was an increase in the quantity of logbook data providing estimates of catch in weight and numbers. This enables us to examine the average fish weight by season and area. Data from 2012-2014 were combined to increase sample sizes. To further increase sample size, areas were aggregated into BS/AI, CG/WGOA, and WY/EY/SE (EGOA). Data were included unless there was missing weight or count information. There were very small differences between spring, summer, and fall in the west and central areas and larger differences in the EGOA (see figure below). In EGOA, weight in spring was $6.1 \mathrm{lbs}, 7.1 \mathrm{lbs}$ in summer, and 8.0 lbs in fall. Although fish size increases in the fall, catch rates and effort decreases.

Count of hook and line logbook sets used for calculations of average weight by area and season.

| Area | $\underline{\text { Spring }}$ | $\underline{\text { Summer }}$ | $\underline{\text { Fall }}$ | $\underline{\text { Total }}$ |
| :--- | :---: | :---: | :---: | :---: |
| BS/AI | 1,255 | 925 | 445 | 2,625 |
| CG/WG | 2,203 | 1,797 | 595 | 4,595 |
| EGOA | 1,419 | 365 | 166 | 1,950 |

## Pot fishery catch rate analysis

Pot catch rates: Because pot data are sparser than longline data, and in some years is confidential due to fewer than 3 vessels participating, specific annual data are not presented. In addition, it is difficult to discern trends, since pot catch rates have wider confidence intervals than longline data due to smaller
sample sizes. Observed sets are determined to be targeting sablefish if sablefish comprise the greatest weight in the set. Overall, there are more vessels in both the logbook and observer data from the sablefish pot fishery in the BS than the AI. Since 2006, in the BS there have been from 3 to 9 vessels in logbook data and 5 to 8 vessels in observer data. In the AI, there have been from 1 to 5 vessels in logbooks and 1 to 4 in observer data.

In logbook data, since 2009 the number of pots, sets, and vessels has decreased. For example, in logbooks in 2014, only 276 sets were reported in the BS and 1,284 in 2009. From 2006-2014 the average catch rate in logbook data was $29 \mathrm{lbs} /$ pot in the AI (number sets $(\mathrm{n})=1,271)$ and $18 \mathrm{lbs} / \mathrm{pot}$ in the $\mathrm{BS}(\mathrm{n}=3,237)$. The average catch rate in the observer data from 2006-2014 was $11 \mathrm{lbs} / \mathrm{pot}(\mathrm{n}=1,156)$ in the AI and 18 $\mathrm{lbs} / \mathrm{pot}(\mathrm{n}=2,970)$ in the BS. The effort recorded by observers has also been decreasing since 2009 in the BS and 2011 in the AI. Pot effort is approximately equal throughout the fishing season, unlike hook and line fishing where effort is highest in the spring.

The composition of bycatch species caught in observed pots that retained sablefish in the BS and AI is comprised mostly of arrowtooth/Kamchatka flounder, Greenland turbot, Pacific halibut, giant grenadier, and snails. The estimated catch of golden king crab in the pot fishery was high in 2009 (Hanselman et al. 2010), but in 2014 it was $98 \%$ lower than 2009.

## Surveys

A number of fishery independent surveys catch sablefish. The survey indices included in the model for this assessment are the AFSC longline survey and the AFSC GOA bottom trawl survey. For other surveys that occur in the same or adjacent geographical areas, but are not included as separate indices in the model, we provide trends and comparative analyses to the AFSC longline survey. Research catch removals including survey removals are documented in Appendix 3B.

## AFSC Surveys

## Longline survey

Overview: Catch, effort, age, length, weight, and maturity data are collected during sablefish longline surveys. These longline surveys likely provide an accurate index of sablefish abundance (Sigler 2000). Japan and the United States conducted a cooperative longline survey for sablefish in the GOA annually from 1978 to 1994, adding the AI region in 1980 and the eastern BS in 1982 (Sasaki 1985, Sigler and Fujioka 1988). Since 1987, the Alaska Fisheries Science Center has conducted annual longline surveys of the upper continental slope, referred to as domestic longline surveys, designed to continue the time series of the Japan-U.S. cooperative survey (Sigler and Zenger 1989). The domestic longline survey began annual sampling of the GOA in 1987, biennial sampling of the AI in 1996, and biennial sampling of the eastern BS in 1997 (Rutecki et al. 1997). The domestic survey also samples major gullies of the GOA in addition to sampling the upper continental slope. The order in which areas are surveyed was changed in 1998 to reduce interactions between survey sampling and short, intense fisheries. Before 1998, the order was AI and/or BS, Western Gulf, Central Gulf, Eastern Gulf. Starting in 1998, the Eastern Gulf area was surveyed before the Central Gulf area.
Specimen collections: Sablefish length data were randomly collected for all survey years. Otoliths were collected for age determination for most survey years. From 1979-1994 otolith collections were lengthstratified; since 1994 otoliths have been collected randomly. Prior to 1996, otolith collections were aged but not consistently from year to year. Since 1996, a sample of otoliths collected during each survey has been aged in the years they were collected. Approximately one-half of the otoliths collected $(\sim 1,000)$ are aged annually. This sample size for age compositions should be large enough to get a precise age composition for the whole survey area, but may be too small to estimate the age composition in smaller areas by sex (P. Hulson, unpublished manuscript).
Standardization: Kimura and Zenger (1997) compared the performance of the two surveys from 1988 to

1994 in detail, including experiments comparing hook and gangion types used in the two surveys. The abundance index for both longline surveys decreased from 1988 to 1989, the cooperative survey decreased from 1989 to 1990, while the domestic survey increased (Table 3.9). Kimura and Zenger (1997) attributed the difference to the domestic longline survey not being standardized until 1990.

Survey Trends: Relative population abundance indices are computed annually using survey catch rates from stations sampled on the continental slope. Highest sablefish abundance indices occurred during the Japan-U.S. cooperative survey in the mid-1980's, in response to exceptional recruitment in the late 1970's (Figure 3.7). Relative population numbers declined through the 1990's in most areas during the domestic longline survey. Catches increased in the early 2000's but have trended down since 2006.

The 2013 and 2015 survey estimates of relative abundance in numbers (RPN) are the lowest points in the domestic time series despite modest increases in 2010, 2011 and 2014.The index is remains below average because of recent weak recruitment.

Whale Depredation: Killer whale depredation of the survey's sablefish catches has been a problem in the BS since the beginning of the survey (Sasaki 1987). Killer whale depredation primarily occurs in the BS, AI, WGOA, and to a lesser extent in recent years in the CGOA (Table 3.11). Depredation is easily identified by reduced sablefish catch and the presence of lips or jaws and bent, straightened, or broken hooks. Since 1990, portions of the gear at stations affected by killer whale depredation during the domestic longline survey have been excluded from the analysis of catch rates, RPNs, and RPWs. The AI and the BS were added to the domestic longline survey in 1996 and this is when killer whale depredation increased. In 2009, 10 BS stations were depredated, which significantly impacted catch and biased the abundance index leading to using the 2007 BS RPN estimate to interpolate the 2009 and 2010 BS RPNs (Hanselman et al. 2009). In 2011, depredation levels in the BS were similar to previous years with catches at 7 of 16 stations affected. In 2013, a new high of 11 stations were depredated, although fewer skates were impacted and therefore removed from the analysis in comparison to what occurred in 2009. In the AI depredation was highest in 2012 and in 2014 was back to levels seen in 2008 and 2010.

In 2015 killer whale depredation was similar to recent years (Table 3.11). The number of station in the BS was down to 9 from 11 stations in 2013. Although there has been some killer whale depredation in the CGOA in the past (1-2 stations), this year there was none.

Sperm whale depredation affects longline catches, but evidence of depredation is not accompanied by obvious decreases in sablefish catch or common occurrence of lips and jaws or bent and broken hooks. Data on sperm whale depredation have been collected since the 1998 longline survey (Table 3.11). Sperm whales are often observed from the survey vessel during haulback but do not appear to be depredating on the catch. Sperm whale depredation and presence is recorded during the longline survey at the station level, not the skate level like killer whales. Depredation is defined as sperm whales being present during haulback with the occurrence of damaged fish in the catch.
Sperm whale depredation is variable, but has generally been increasing since 1998 (Table 3.11). Whales are most common in the EGOA (WY and EY/SE), but are also seen in the CGOA. In 2015 there were sperm whales depredating at 19 stations (annual range 4-21) (Table 3.11). In 2015 in the CGOA sperm whales were present at 9 stations and depredating at 6 , which is higher than in other years. Although sperm whales are sometimes observed in the WGOA, in 2015 there were no sightings.
Multiple studies have attempted to quantify sperm whale depredation rates. An early study using data collected by fisheries observers in Alaskan waters found no significant effect on the commercial fishery catch (Hill et al. 1999). Another study using data collected from commercial vessels in southeast Alaska, found a small, significant effect comparing longline fishery catches between sets with sperm whales present and sets with sperm whales absent ( $3 \%$ reduction, $95 \% \mathrm{CI}$ of ( $0.4-5.5 \%$ ), t-test, $p=0.02$, Straley et al. 2005).

A general linear model fit to longline survey data from 1998-2004 found neither sperm whale presence ( $p$
$=0.71$ ) nor depredation rate $(p=0.78)$ increased significantly from 1998 to 2004. Catch rates were about $2 \%$ less at locations where depredation occurred, but the effect was not significant ( $p=0.34$ ). This analysis was updated through 2009 and now shows a significant effect of approximately four kilograms per hundred hooks in the Central and Eastern Gulf regions, which translates into approximately a $2 \%$ decrease in overall catch in those areas (J. Liddle, October, 2009, pers. comm.). A retrospective analysis of this data indicates the effect is not significant until the 2009 data are added, indicating the increasing depredation effect has combined with accumulating survey data to give increased power to detect this small reduction in CPUE.

Longline survey catch rates are not adjusted for sperm whale depredation because we do not know when measureable depredation began during the survey time series, because past studies of depredation on the longline survey showed no significant effect, and because sperm whale depredation is difficult to detect (Sigler et al. 2007). Because of recent increases in sperm whale presence and depredation at survey stations, as indicated by whale observations and significant results of recent studies, we evaluated a statistical adjustment to survey catch rates using a general linear modeling approach (Appendix 3C, Hanselman et al. 2010). This approach had promise but had issues with variance estimation and autocorrelation between samples. A new approach has been developed using a generalized linear mixed model that resolves these issues (see Appendix 3C in Hanselman et al. 2014).

Gully Stations: In addition to the continental slope stations sampled during the survey, twenty-seven stations are sampled in gullies at the rate of one to two stations per day. The sampled gullies are Shelikof Trough, Amatuli Gully, W-grounds, Yakutat Valley, Spencer Gully, Ommaney Trench, Dixon Entrance, and one station on the continental shelf off Baranof Island. The majority of these stations are located in deep gully entrances to the continental shelf in depths from $150-300 \mathrm{~m}$ in areas where the commercial fishery targets sablefish. No gullies are currently sampled in the Western GOA, AI, or BS.

Previous analyses have shown that on average gully stations catch fewer large fish and more small fish than adjacent slope stations (Rutecki et al. 1997, Zenger et al. 1994). Compared with the adjacent regions of the slope, sablefish catch rates for gully stations have been mixed with no significant trend (Zenger et al. 1994). Gully catches may indicate recruitment signals before slope areas because of their shallow depth, where younger, smaller sablefish typically inhabit. Catch rates from these stations have not been included in the historical abundance index calculations because preferred habitat of adult sablefish is on the slope.
These areas do support significant numbers of sablefish, however, and are important areas sampled by the survey. We compared the RPNs of gully stations to the RPNs of slope stations in the GOA to see if catches were comparable, or more importantly, if they portrayed different trends than the RPNs used in this assessment.
To compare trends, we computed Student's- $t$ normalized residuals for all GOA gullies and slope stations and plotted them for the time series. If the indices were correlated, then the residuals would track one another over time (Figure 3.8). Overall, gully catches in the GOA from 1990-2014 are moderately correlated with slope catches ( $r=0.55$ ). There is no evidence of major differences in trends. In regards to gully catches being a recruitment indicator, the increase in the gully RPNs in 1999 and 2001-2002 may be in response to the above average 1997 and 2000 year classes. Both the 2001 and 2002 RPNs for the gully stations are higher than in 1999, which supports the current model estimate that the 2000 year class was larger than 1997. Both gully and slope trends were down in 2012 and 2013, consistent with the overall decrease in survey catch. However, the slope stations increased in 2014, while the gullies continued to decline. In 2015, the opposite pattern occurred, with the gullies showing a slight uptick while the slope stations declined again. In the future, we will continue to explore sablefish catch rates in gullies and explore their usefulness for indicating recruitment; they may also be useful for quantifying depredation, since sperm whales have rarely depredated on catches from gully stations.
Interactions between the fishery and survey are described in Appendix 3A.

## Trawl surveys

Trawl surveys of the upper continental slope that adult sablefish inhabit have been conducted biennially or triennially since 1980 in the AI, and 1984 in the GOA, always to 500 m and occasionally to 700-1000 m . Trawl surveys of the BS slope were conducted biennially from 1979-1991 and redesigned and standardized for $2002,2004,2008,2010$, and 2012. Trawl surveys of the BS shelf are conducted annually but generally catch no sablefish. Trawl survey abundance indices were not used in the assessment model prior to 2007 in the sablefish assessment because they were not considered good indicators of the sablefish relative abundance. However, there is a long time series of data available and given the trawl survey's ability to sample smaller fish, it may be a better indicator of recruitment than the longline survey.

There is some difficulty with combining estimates from the BS and AI with the GOA estimates since they occur on alternating years. A method could be developed to combine these indices, but it leaves the problem of how to use the length data to predict recruitment since the data could give mixed signals on year class strength. At this time we are using only the GOA trawl survey biomass estimates ( $<500 \mathrm{~m}$ depth, Figure 3.4) and length data ( $<500 \mathrm{~m}$ depth) as a recruitment index for the whole population. The largest proportion of sablefish biomass is in the GOA so it should be indicative of the overall population. Biomass estimates used in the assessment for 1984-2013 are shown in Table 3.10. The GOA trawl survey index was at its lowest level of the time series in 2013, but increased $12 \%$ in 2015 from the 2013 estimate.

AI and BS Slope survey biomass estimates are not used in the assessment model but are tracked in Figure 3.9. Estimates in the two areas have decreased slowly since 2000.

## Other surveys/areas not used in the assessment model

## IPHC Longline Surveys

The IPHC conducts a longline survey each year to assess Pacific halibut. This survey differs from the AFSC longline survey in gear configuration and sampling design, but catches substantial numbers of sablefish. More information on this survey can be found in Soderlund et al. (2009). A major difference between the two surveys is that the IPHC survey samples the shelf consistently from $\sim 10-500$ meters, whereas the AFSC survey samples the slope and select gullies from 200-1000 meters. Because the majority of effort occurs on the shelf in shallower depths, the IPHC survey may catch smaller and younger sablefish than the AFSC survey; however, lengths of sablefish are not taken on the IPHC survey.
For comparison to the AFSC survey, IPHC relative population number's (RPN) were calculated using the same methods as the AFSC survey values, the only difference being the depth stratum increments. Area sizes used to calculate biomass in the RACE trawl surveys were utilized for IPHC RPN calculations.
We do not obtain IPHC survey estimates for the current year until the following year. We compared the IPHC and the AFSC RPNs for the GOA (Figure 3.10). The two series track well, but the IPHC survey RPN has more variability. This is likely because it surveys shallower water on the shelf where younger sablefish reside and are more patchily distributed. Since the abundance of younger sablefish will be more variable as year classes pass through, the survey more closely resembles the NMFS GOA trawl survey index described above which samples the same depths (Figure 3.10b).

While the two longline surveys have shown consistent patterns for most years, they diverged in 2010 and 2011, but the 2013 estimates both show the lowest point in the time series for each index (Figure 3.10 ). The IPHC estimate for the Gulf of Alaska for 2013 was a $21 \%$ decline from 2012. The uptick seen in 2014 in the AFSC survey was not apparent in the IPHC survey. We will continue to examine trends in each region and at each depth interval for evidence of recruiting year classes and for comparison to the AFSC longline survey. There is some effort in depths shallower than 200 meters on the AFSC longline survey, and we recently have computed RPNs for these depths for future comparisons with the IPHC RPNs.

## Alaska Department of Fish and Game

The Alaska Department of Fish and Game conducts mark-recapture and a longline survey in Northern Southeast Alaska Inside (NSEI) waters. Sablefish in this area are treated as a separate population, but some migration into and out of Inside waters has been confirmed with tagging studies (Hanselman et al. 2015). This population seems to be stabilizing from previous steep declines. Their longline survey CPUE estimates (Figure 3.11a) and fishery CPUE estimates (Figure 3.11b) had been slowly increasing since 2000, confirming the lows in 1999/2000 estimated in our assessment. Like the AFSC longline survey, there was a sharp decline in the 2013 longline survey CPUE estimates for NSEI and a slight uptick in 2014.

## Department of Fish and Oceans of Canada

In a 2011 Science Advisory Report, DFO reported :"Stock reconstructions suggest that stock status is currently below $B_{M S Y}$ for all scenarios, with the stock currently positioned in the mid-Cautious to lowHealthy zones." Under these scenarios, recent harvest rates on adult sablefish potentially have been between $0.06-0.15^{1}$.

The stratified random trap survey was up approximately $29 \%$ from 2012 to 2013 after a time series low in 2012 (see figure below) but has registered a new time series low in 2014. The estimated biomass trend in B.C. is similar to the trend in Alaska (see figure below) ${ }^{2}$. The similarly low abundance south of Alaska concerns us, and points to the need to better understand the contribution to Alaska sablefish productivity from B.C. sablefish. Some potential ideas are to conduct an area-wide study of sablefish tag recoveries, and to attempt to model the population to include B.C. sablefish and U.S. West Coast sablefish.

[^0]
## Overall abundance trends

Relative abundance has cycled through three valleys and two peaks near 1970 and 1985 (Table 3.10, Figures 3.3 and 3.4). The post-1970 decrease likely is due to heavy fishing. The 1985 peak likely is due to the exceptionally large late 1970's year classes. Since 1988, relative abundance has decreased substantially. Regionally, abundance decreased faster in the BS, AI, and western GOA and more slowly in the central and eastern GOA (Figure 3.7). The majority of the surveys show that sablefish were at their lowest levels in the early 2000s, with current abundance reaching these lows again in 2014 in the central and eastern GOA, and in 2015 in the western areas.

## Analytic approach

## Model Structure

The sablefish population is assessed with an age-structured model. The analysis presented here extends earlier age structured models developed by Kimura (1990) and Sigler (1999), which all stem from the work by Fournier and Archibald (1982). The current model configuration follows a more complex version of the GOA Pacific ocean perch model (Hanselman et al. 2005a); it includes split sexes and many more data sources to attempt to more realistically represent the underlying population dynamics of sablefish. The current configuration was accepted by the Groundfish Plan Team and NPFMC in 2010 ("Moonwater", Hanselman et al. 2010). The population dynamics and likelihood equations are described in Box 1. The analysis was completed using AD Model Builder software, a C++ based software for development and fitting of general nonlinear statistical models (Fournier et al. 2012).

## Parameters Estimated Outside the Assessment Model

The following table lists the parameters estimated independently:

| Parameter name | Value Value | Source |
| :---: | :---: | :---: |
| Time period | 1960-1995 $\quad$ 1996-current |  |
| Natural mortality | 0.10 .1 | Johnson and Quinn (1988) |
| Female maturity-at-age | $m_{a}=1 /\left(1+e^{-0.84(a-6.60)}\right)$ | Sasaki (1985) |
| Length-at-age - females | $\bar{L}_{a}=75.6\left(1-e^{-0.208(a+3.63)}\right) \quad \bar{L}_{a}=80.2\left(1-e^{-0.222(a+1.95)}\right)$ | Hanselman et al. (2007) |
| Length-at-age - males | $\bar{L}_{a}=65.3\left(1-e^{-0.227(a+4.09)}\right) \quad \bar{L}_{a}=67.8\left(1-e^{-0.290(a+2.27)}\right)$ | Hanselman et al. (2007) |
| Weight-at-age - females | $\ln \hat{W}_{a}=\ln (5.47)+3.02 \ln \left(1-e^{-0.238(a+1.39)}\right)$ | Hanselman et al. (2007) |
| Weight-at-age - males | $\ln \hat{W}_{a}=\ln (3.16)+2.96 \ln \left(1-e^{-0.356(a+1.13)}\right)$ | Hanselman et al. (2007) |
| Ageing error matrix | From known-age tag releases, extrapolated for older ages | Heifetz et al. <br> (1999) |
| Recruitment variability ( $\sigma_{r}$ ) | 1.2 1.2 | Sigler et al. (2002) |

Age and Size of Recruitment: Juvenile sablefish rear in nearshore and continental shelf waters, moving to the upper continental slope as adults. Fish first appear on the upper continental slope, where the longline survey and longline fishery occur, at age 2 , and a fork length of about 45 cm . A higher proportion of young fish are susceptible to trawl gear compared to longline gear because trawl fisheries usually occur on the continental shelf and shelf break inhabited by younger fish, and catching small sablefish may be hindered by the large bait and hooks on longline gear.
Sablefish are difficult to age, especially those older than eight years (Kimura and Lyons 1991). To compensate, we use an ageing error matrix based on known-age otoliths (Heifetz et al. 1999; Hanselman
et al. 2012).
Growth and maturity: Sablefish grow rapidly in early life, growing $1.2 \mathrm{~mm} \mathrm{~d}^{-1}$ during their first spring and summer (Sigler et al. 2001). Within 100 days after first increment (first daily otolith mark for larvae) formation, they average 120 mm . Sablefish are currently estimated to reach average maximum lengths and weights of 68 cm and 3.2 kg for males and 80 cm and 5.5 kg for females (Echave et al. 2012).

New growth relationships were estimated in 2007 because many more age data were available (Hanselman et al. 2007); this analysis was accepted by the Plan Team in November 2007 and published in 2012 (Echave et al. 2012). We divided the data into two time periods based on the change in sampling design that occurred in 1995. It appears that sablefish maximum length and weight has increased slightly over time. New age-length conversion matrices were constructed using these curves with normal error fit to the standard deviations of the collected lengths at age (Figure 3.12). These new matrices provided for a superior fit to the data. Therefore, we use a bias-corrected and updated growth curve for the older data (1981-1993) and a new growth curve describing recent randomly collected data (1996-2004).

Fifty percent of females are mature at 65 cm , while 50 percent of males are mature at 57 cm (Sasaki 1985), corresponding to ages 6.6 for females and 5 for males (Table 3.12). Maturity parameters were estimated independently of the assessment model and then incorporated into the assessment model as fixed values. The maturity - length function is $m_{l}=1 /\left(1+e^{-0.40(L-57)}\right)$ for males and $m_{l}=1 /\left(1+e^{-0.40(L-}\right.$ ${ }^{65)}$ ) for females. Maturity at age was computed using logistic equations fit to the length-maturity relationships shown in Sasaki (1985, Figure 23, GOA). Prior to the 2006 assessment, average male and female maturity was used to compute spawning biomass. Beginning with the 2006 assessment, femaleonly maturity has been used to compute spawning biomass. Female maturity-at-age from Sasaki (1985) is described by the logistic fit of $m_{a}=1 /\left(1+e^{-0.84(a-6.60)}\right)$. In 2011, the AFSC conducted a winter cruise out of Kodiak to sample sablefish when they are preparing to spawn. Ovaries were examined histologically to determine maturity for a study of the age at maturity and fecundity. Skipped spawning was documented for the first time in sablefish. These winter samples provided a similar age at $50 \%$ maturity estimate ( 6.8 years) as the mean of visual observations taken during summer surveys from 1996-2012 (mean = 7.0 years) and the estimate currently used in the assessment (mean $=6.6$ years), when skipped spawners were classified as mature. Skipped spawners were primarily found in gullies on the shelf and was positively correlated with age. A second survey will take place in December 2015 in the same areas that were sampled in 2011. Future analyses will aim to develop and evaluate methods to incorporate skipped spawning into maturity ogives and to better utilize the time series of visual maturity estimates.
Maximum age and natural mortality: Sablefish are long-lived; ages over 40 years are regularly recorded (Kimura et al. 1993). Reported maximum age for Alaska is 94 years (Kimura et al. 1998). Canadian researchers report age determinations up to 113 years ${ }^{1}$. A natural mortality rate of $M=0.10$ has been assumed for previous sablefish assessments, compared to $M=0.112$ assumed by Funk and Bracken (1984). Johnson and Quinn (1988) used values of 0.10 and 0.20 in a catch-at-age analysis and found that estimated abundance trends agreed better with survey results when $M=0.10$ was used. Natural mortality has been modeled in a variety of ways in previous assessments. For sablefish assessments before 1999, natural mortality was assumed to equal 0.10 . For assessments from 1999 to 2003, natural mortality was estimated rather than assumed to equal 0.10 ; the estimated value was about 0.10 but only with a precise prior imposed. For the 2004 assessment, a more detailed analysis of the posterior probability showed that natural mortality was not well-estimated by the available data (Sigler et al. 2004). Therefore in 2006, we returned to fixing the parameter at 0.10 .
Variance and effective sample sizes: Several quantities were computed in order to compare the variance of the residuals to the assumed input variances. The standardized deviation of normalized residuals

[^1](SDNR) is closely related to the root mean squared error (RMSE) or effective sample size; values of SDNR of approximately 1 indicate that the model is fitting a data component as well as would be expected for a given specified input variance. The normalized residuals for a given year $i$ of the abundance index was computed as
$$
\delta_{i}=\frac{\ln \left(I_{i}\right)-\ln \left(\hat{I}_{i}\right)}{\sigma_{i}}
$$
where $\sigma_{i}$ is the input sampling log standard deviation of the estimated abundance index. For age or length composition data assumed to follow a multinomial distribution, the normalized residuals for age/length group $a$ in year $i$ were computed as
$$
\delta_{i, a}=\frac{\left(y_{i, a}-\hat{y}_{i, a}\right)}{\sqrt{\hat{y}_{i, a}\left(1-\hat{y}_{i, a}\right) / n_{i}}}
$$
where $y$ and $\hat{y}$ are the observed and estimated proportion, respectively, and $n$ is the input assumed sample size for the multinomial distribution. The effective sample size was also computed for the age and length compositions modeled with a multinomial distribution, and for a given year $i$ was computed as
$$
E_{i}=\frac{\sum_{a} \hat{y}_{a} *\left(1-\hat{y}_{a}\right)}{\sum_{a}\left(\hat{y}_{a}-y_{a}\right)^{2}}
$$

An effective sample size that is nearly equal to the input sample size can be interpreted as having a model fit that is consistent with the input sample size.

For the 2010 recommended assessment model, we used average SDNR as a criterion to help reweight the age and length compositions. SDNR is a common metric used for goodness of fit in other fisheries, particularly in New Zealand (e.g. Langley and Maunder 2009) and has been recommended for use in fisheries models in Alaska during multiple CIE reviews, such as Atka mackerel and rockfish. We iteratively reweighted the model by setting an objective function penalty to reduce the deviations of average SDNR of a data component from one. Initially, we tried to fit all multinomial components this way, but due to tradeoffs in fit, it was found that the input sample sizes became too large and masked the influence of important data such as abundance indices. Given that we have age and length samples from nearly all years of the longline surveys, we chose to eliminate the attempt to fit the length data well enough to achieve an average SDNR of one, and reweighted all age components and only length components where no age data exists (e.g. domestic trawl fishery). The abundance index SDNRs were calculated, but no attempt was made to adjust their input variance because we have a priori knowledge about their sampling variances. This process was completed before the 2010 data were added into the assessment and endorsed by the Plan Teams and SSC in 2010. We continue to use these weightings. The table below shows the input $\mathrm{CVs} /$ sample sizes for the data sources and their associated output SDNR for the recommended model. This reweighting is intended to remain fixed for at least several years. The data weights in general continue to do well by these objectives (Table 3.13).

## Parameters Estimated Inside the Assessment Model

Below is a summary of the parameters estimated within the recommended assessment model:

| Parameter name | Symbol | Number of |
| :--- | ---: | ---: |
| Catchability | $q$ | 6 |
| Log-mean-recruitment | $\mu_{r}$ | 1 |
| Spawners-per-recruit levels | $F_{35}, F_{40}, F_{50}$ | 3 |
| Recruitment deviations | $\tau_{y}$ | 83 |
| Average fishing mortality | $\mu_{f}$ | 2 |
| Fishing mortality deviations | $\phi_{y}$ | 112 |
| Fishery selectivity | $f s_{a}$ | 8 |
| Survey selectivity | $s s_{a}$ | 7 |
| Total |  | 222 |

Catchability is separately estimated for the Japanese longline fishery, the cooperative longline survey, the domestic longline survey, U.S. longline derby fishery, U.S. longline IFQ fishery, and the NMFS GOA trawl survey. Information is available to link these estimates of catchability. Kimura and Zenger (1997) analyzed the relationship between the cooperative and domestic longline surveys. For assessments through 2006, we used their results to create a prior distribution which linked catchability estimates for the two surveys. For 2007, we estimated new catchability prior distributions based on the ratio of the various abundance indices to a combined Alaskan trawl index. This resulted in similar mean estimates of catchability to those previously used, but allowed us to estimate a prior variance to be used in the model. This also facilitates linking the relative catchabilities between indices. These priors were used in the recommended model for 2008. This analysis was presented at the September 2007 Plan Team and is presented in its entirety in Hanselman et al. (2007). Lognormal prior distributions were used with the parameters shown below:

| Index | U.S. LL Survey | Jap. LL Survey | Fisheries | GOA Trawl |
| :---: | :---: | :---: | :---: | :---: |
| Mean | 7.857 | 4.693 | 4.967 | 0.692 |
| CV | 33\% | 24\% | 33\% | 30\% |

Recruitment is not estimated with a stock-recruit relationship, but is estimated with a level of average recruitment with deviations from average recruitment for the years 1933-2014.
Fishing mortality is estimated with two average fishing mortality parameters for the two fisheries (fixed gear and trawl) and deviations from the average for years 1960-2015 for each fishery.
Selectivity is represented using a function and is separately estimated by sex for the longline survey, fixed-gear fishery (pot and longlines combined), and the trawl survey. Selectivity for the longline surveys and fixed-gear fishery is restricted to be asymptotic by using the logistic function. Selectivity for the trawl fishery and trawl survey are dome-shaped (right descending limb) and estimated with a two-parameter gamma-function and a power function respectively (see Box 1 for equations). This right-descending limb is allowed because we do not expect that the trawl survey and fishery will catch older aged fish as frequently because they fish shallower than the fixed-gear fishery. Selectivity for the fixed-gear fishery is estimated separately for the "derby" fishery prior to 1995 and the IFQ fishery from 1995 thereafter. Fishers may choose where they fish in the IFQ fishery, compared to the crowded fishing grounds during the 1985-1994 "derby" fishery, when fishers reportedly often fished in less productive depths due to crowding (Sigler and Lunsford 2001). In choosing their ground, they presumably target bigger, older fish, and depths that produce the most abundant catches.

## Bayesian analysis of reference points

Since the 1999 assessment, we have conducted a limited Bayesian analysis of assessment uncertainty. The
posterior distribution was computed based on 10 million MCMC simulations drawn from the posterior distribution. A burn-in of 1 million draws was removed from the beginning of the chain and then thinned to 4,000 parameter draws to remove serial correlation between successive draws. This was determined to be sufficient through simple chain plots, and comparing the means and standard deviations of the first half of the chain with the second half.

In previous assessments, we estimated the posterior probability that projected abundance will fall below the decision analysis thresholds based on Mace and Sissenwine (1993). However, in the North Pacific Fishery Management Council setting we have thresholds that are defined in the Council harvest rules. These are when the spawning biomass falls below $B_{40 \%}, B_{35 \%}$, and when the spawning biomass falls below $1 / 2$ MSY or $B_{17.5 \%}$ which calls for a rebuilding plan under the Magnuson-Stevens Act. For the previous analysis based on Mace and Sissenwine (1993), see Hanselman et al. 2005b. To examine the posterior probability, we project spawning biomass into the future with recruitments varied as random draws from a lognormal distribution with the mean and standard deviation of 1979-2013 age-2 recruitments. The fishing mortality used is the current yield ratio described in the Catch specification section multiplied by maxABC for each year.

## Box 1 Model Description

$Y \quad$ Year, $y=1,2, \ldots T$
$T \quad$ Terminal year of the model
$A \quad$ Model age class, $a=a_{0}, a_{0}+1, \ldots, a_{+}$
$a_{0} \quad$ Age at recruitment to the model
$a_{+} \quad$ Plus-group age class (oldest age considered plus all older ages)
$L \quad$ Length class
$\Omega \quad$ Number of length bins (for length composition data)
$G \quad$ Gear-type ( $g$ = longline surveys, longline fisheries, or trawl fisheries)
$X \quad$ Index for likelihood component
$w_{a, s} \quad$ Average weight at age $a$ and sex $s$
$\varphi_{a} \quad$ Proportion of females mature at age $a$
$\mu_{r} \quad$ Average log-recruitment
$\mu_{f} \quad$ Average log-fishing mortality
$\phi_{y, g} \quad$ Annual fishing mortality deviation
$\tau_{y} \quad$ Annual recruitment deviation $\sim \ln \left(0, \sigma_{r}\right)$
$\sigma_{r} \quad$ Recruitment standard deviation
$N_{y, a, s} \quad$ Numbers of fish at age $a$ in year $y$ of sex $s$
$M \quad$ Natural mortality
$F_{y, a, g} \quad$ Fishing mortality for year $y$, age class $a$ and gear $g$
$Z_{y, a} \quad$ Total mortality for year $y$ and age class $a\left(=\sum_{g} F_{y, a, g}+M\right)$
$R_{y} \quad$ Recruitment in year $y$
$B_{y} \quad$ Spawning biomass in year $y$
$s_{a, s}^{g} \quad$ Selectivity at age $a$ for gear type $g$ and sex $s$
$A_{50 \%}, d_{50 \%}$ Age at 50\% selection for ascending limb, age at $50 \%$ deselection for descending limb
$\delta \quad$ Slope/shape parameters for different logistic curves
A Ageing-error matrix dimensioned $a_{+} \times a_{+}$
$\mathbf{A}_{s}{ }^{l} \quad$ Age to length conversion matrix by sex $s$ dimensioned $a_{+} \times \Omega$
$q_{g} \quad$ Abundance index catchability coefficient by gear
$\lambda_{x} \quad$ Statistical weight (penalty) for component $x$
$I_{y}, \hat{I}_{y} \quad$ Observed and predicted survey index in year $y$
$P_{y, l, s}^{g}, \hat{P}_{y, l, s}^{g}$ Observed and predicted proportion at length $l$ for gear $g$ in year $y$ and sex $s$
$P_{y, a, s}^{g}, \hat{P}_{y, a, s}^{g}$ Observed and predicted proportion at observed age $a$ for gear $g$ in year $y$ and sex $s$
$\psi_{y}^{g} \quad$ Sample size assumed for gear $g$ in year $y$ (for multinomial likelihood)
$n_{g} \quad$ Number of years that age (or length) composition is available for gear $g$
$q_{\mu, g}, \sigma_{q, g} \quad$ Prior mean, standard deviation for catchability coefficient for gear $g$
$M_{\mu}, \sigma_{M} \quad$ Prior mean, standard deviation for natural mortality
$\sigma_{r_{\mu}}, \sigma_{\sigma_{r}} \quad$ Prior mean, standard deviation for recruitment variability

| Equations describing state dynamics | Model Description (continued) |
| :---: | :---: |

## Results

## Model Evaluation

For this assessment, we present last year's model updated for 2015 with no model changes. A comparison of the model likelihood components and key parameter estimates from 2014 are compared with the 2015 updated model.

Box 2: Model comparison of the 2014 (M0) and 2015 (M1) models by contribution to the objective function (negative log-likelihood values) and key parameters.

| $\sigma_{r}$ (recruitment variability) | 1.20 | 1.20 |

The two models are identical in all aspects except for inclusion of new data. Our usual criteria for choosing a superior model are: (1) the best overall fit to the data (in terms of negative log-likelihood), (2) biologically reasonable patterns of estimated recruitment, catchabilities, and selectivities, (3) a good visual fit to length and age compositions, and (4) parsimony.

Because the models presented have different amounts of data and different data weightings, it is not reasonable to compare their negative log likelihoods so we cannot compare them by the first criterion above. In general we can only evaluate the 2015 model based on changes in results from 2014 and it is unlikely we would reject the model that included the most recent data. The model generally produces good visual fits to the data, and biologically reasonable patterns of recruitment, abundance, and selectivities. An exception to the generally good fits to the data is the fit to the recent fishery age compositions, which fit the plus group poorly (see further discussion in Goodness of fit below). The 2015 update shows a slight decrease in spawning and total biomass from previous projections. Therefore the 2015 (M1) model is utilizing the new information effectively, and we use it to recommend 2016 ABC and OFL.

## Time Series Results

## Definitions

Spawning biomass is the biomass estimate of mature females. Total biomass is the estimate of all sablefish age-two and greater. Recruitment is measured as the number of age-two sablefish. Fishing mortality is fully-selected F, meaning the mortality at the age the fishery has fully selected the fish.

## Abundance trends

Sablefish abundance increased during the mid-1960's (Table 3.15, Figure 3.13) due to strong year classes in the early 1960's. Abundance subsequently dropped during the 1970's due to heavy fishing and relatively low recruitment; catches peaked at $53,080 \mathrm{t}$ in 1972. The population recovered due to a series of strong year classes from the late 1970's (Figure 3.14, Table 3.14) and also recovered at different rates in different areas (Table 3.15); spawning abundance peaked again in 1987. The population then decreased because these strong year classes expired. The model suggested an increasing trend in spawning biomass since the all-time low in 2002, which changed directions again in 2008 (Figure 3.13). The low 2012-2013 longline survey RPN values changed what was a stable trend in 2011 to a downward trajectory in 2015.
Projected 2016 spawning biomass is $\mathbf{3 4 \%}$ of unfished spawning biomass. Spawning biomass has increased from a low of $33 \%$ of unfished biomass in 2002 to $42 \%$ in 2008 and has now declined back to $34 \%$ of unfished biomass projected for 2016. The 1997 year class has been an important contributor to the population; however, it has been reduced and is predicted to comprise less than $6 \%$ of the 2016 spawning biomass. The last two above-average year classes, 2000 and 2008, classes each comprise $15 \%$ of the projected 2016 spawning biomass. The 2008 year class will be about $75 \%$ mature in 2016. Figure 3.15 shows the relative contribution of each year class to next year's spawning biomass.

## Recruitment trends

Annual estimated recruitment varies widely (Figure 3.14b). The two recent strong year classes in 1997 and 2000 are evident in all data sources. After 2000, few strong year classes are apparent, but the 2008 year class is currently estimated to be the largest since 2000. Few small fish were caught in the 2005 through 2009 trawl surveys, but the 2008 year class appeared in the 2011 trawl survey length composition. Larger one year olds may be showing up in the 2015 trawl survey length composition in the $41-43 \mathrm{~cm}$ bins (Figures 3.16, 3.17). The 2010 and 2011 longline survey age compositions show the 2008 year class appearing relatively strong in all three areas for lightly selected 2 and 3 year old fish (Figures 3.18-3.20). The 2014 survey age composition is dominated by 2007-2008 year classes which make up more than $30 \%$ of the composition. Large year classes often appear in the western areas first and then in subsequent years in the Central and Eastern GOA. While this was true for the 1997 and 2000 year classes,
the 2008 year class is appearing in all areas at approximately the same magnitude at the same time (Figure 3.18).

Average recruitment during 1979-2015 was 16.3 million 2-year-old sablefish per year, which is slightly less than average recruitment during 1958-2015. Estimates of recruitment strength during the 1960s are less certain because they depend on age data from the 1980s with older aged fish that are subject to more ageing error. In addition the size of the early recruitments is based on an abundance index during the 1960s based only on the Japanese fishery catch rate, which may be a weak measure of abundance. The 2008 year class is being estimated at just above average in this year's model. Because of the very low survey abundance indices in 2012, 2013, and 2015, the 2008 year class thus far is only just above average. If the 2008 year class is actually strong, the estimate may increase if the survey abundance estimates become stronger in future years.
Juvenile sablefish are pelagic and at least part of the population inhabits shallow near-shore areas for their first one to two years of life (Rutecki and Varosi 1997). In most years, juveniles have been found only in a few places such as Saint John Baptist Bay near Sitka, Alaska. Widespread, abundant age-1 juveniles likely indicate a strong year class. Abundant age-1 juveniles were reported for the 1960 (J. Fujioka \& H. Zenger, 1995, NOAA, pers. comm.), 1977 (Bracken 1983), 1980, 1984, and 1998 year classes in southeast Alaska, the 1997 and 1998 year classes in Prince William Sound (W. Bechtol, 2004, ADFG, pers. comm.), the 1998 year class near Kodiak Island (D. Jackson, 2004, ADFG, pers. comm.), and the 2008 year class in Uganik Bay on Kodiak Island (P. Rigby, June, 2009, NOAA, pers. comm.). Numerous reports of young of the year being caught in 2014 have been received including large catches in NOAA surface trawl surveys in the EGOA in the summer (W. Fournier, August, 2014, NOAA, pers. comm.) and in Alaska Department of Fish and Game surveys in Prince William Sound (M. Byerly, 2014, ADFG, pers. comm.). Additionally, salmon fishermen in the EGOA reported large quantities of YOY sablefish in the stomachs of troll caught coho salmon in 2014 and 2015. The Gulf of Alaska NMFS bottom trawl survey caught a substantial number of one year old sablefish in 2015, particularly in the Western GOA. These size fish are not large enough or old enough to enter the model estimates. Surface trawl surveys in the Gulf of Alaska also reported finding YOY sablefish in Pacific pomfret stomachs in the summer of 2015 (C. Denenbaum, September 2015, NOAA, pers. comm.). Charter fishermen in the CGOA also reported frequent catches of one year old sablefish in 2015 while targeting coho salmon (K. Echave, September 2015, NOAA, pers. comm.).

Sablefish recruitment varies greatly from year to year (Figure 3.14b), but shows some relationship to environmental conditions. Sablefish recruitment success is related to winter current direction and water temperature; above average recruitment is more common for years with northerly drift or above average sea surface temperature (Sigler et al. 2001). Sablefish recruitment success is also coincidental with recruitment success of other groundfish species. Strong year classes were synchronous for many northeast Pacific groundfish stocks for the 1961, 1970, 1977, and 1984 year classes (Hollowed and Wooster 1992). For sablefish in Alaska, the 1960-1961 and 1977 year classes also were strong. Some of the largest year classes of sablefish occurred when abundance was near the historic low, the 1977-1978 and 1980-1981 year classes (Figures 3.14, 3.21). These strong year classes followed the 1976/1977 North Pacific regime shift. The 1977 year class was associated with the Pacific Decadal Oscillation (PDO) phase change and the 1977 and 1981 year classes were associated with warm water and unusually strong northeast Pacific pressure index (Hollowed and Wooster 1992). Larger than average year classes were produced again in 1997-2000, when the population was low indicating that recruitment is only weakly related to spawning biomass. Some species such as walleye pollock and sablefish may exhibit increased production at the beginning of a new environmental regime, when bottom up forcing prevails and high turnover species compete for dominance, which later shifts to top down forcing once dominance is established (Bailey 2000, Hunt et al. 2002). The large year classes of sablefish indicate that the population, though low, still was able to take advantage of favorable environmental conditions and produce large year classes. Shotwell et al. (2014) used a two-stage model selection process to examine relevant environmental variables that affect recruitment and included them directly into the assessment model. The best model
suggested that colder than average wintertime sea surface temperatures in the central North Pacific represent oceanic conditions that create positive recruitment events for sablefish in their early life history.

## Goodness of fit

The model generally fit the data well. Abundance indices generally track through the middle of the confidence intervals of the estimates (Figures 3.3, 3.4), with the exception of the trawl survey, where predictions are typically lower in the early years and higher in later years. This index is given less weight than the other indices based on higher sampling error so it does not fit as well. Like the trawl survey index, the fishery CPUE does not fit as well as the longline survey, because the index has a higher variance. All age compositions were predicted well, except for not quite reaching the magnitude of the 1997 and 2000 year classes in several years (Figures 3.19, 3.21, 3.24). The model is not fitting the 2008 year class well in 2014 because of its weak presence in the 2013 age composition. The length frequencies from the fixed gear fishery are predicted well in most years, but the model appears to not fit the smallest fish that appear in 2011 (Figure 3.22, 3.23). The fits to the trawl survey and trawl fishery length compositions were generally mediocre, because of the small sample sizes relative to the longline survey and fishery length compositions (Figures 3.16, 3.17., 3.25). The model fit the domestic longline survey lengths poorly in the 1990s, then fit well until 2011 and 2012 where the smallest and largest fish were not fit well (Figures 3.26, 3.27). By 2014, the 2008 year class has grown large enough (in length) to be included in the main groups in the length compositions. The 2013 fixed gear fishery age composition is fit poorly, particularly in the plus group. This was due to an exceptionally high proportion of the catch caught in the AI being older than 30 years old. Examination of the origin of these older fish showed that this shift in fishery age composition was caused by a westward shift of the observed fishery into grounds that are not surveyed by the longline survey where there is an apparent abundance of older fish that are unknown to the model. This problem is similar, but lessened in the 2014 age composition. We will explore methods to consider these shifts in future spatial assessment models.

## Selectivities

We assume that selectivity is asymptotic for the longline survey and fisheries and dome-shaped (or descending right limb) for the trawl survey and trawl fishery (Figure 3.28). The age-of-50\% selection is 3.8 years for females in the longline survey and 3.9 years in the IFQ longline fishery. Females are selected at an older age in the IFQ fishery than in the derby fishery (Figure 3.28). Males were selected at an older age than females in both the derby and IFQ fisheries, likely because they are smaller at the same age. Selection of younger fish during short open-access seasons likely was due to crowding of the fishing grounds, so that some fishers were pushed to fish shallower water that young fish inhabit (Sigler and Lunsford 2001). Relative to the longline survey, younger fish are more vulnerable and older fish are less vulnerable to the trawl fishery because trawling often occurs on the continental shelf in shallower waters ( $<300 \mathrm{~m}$ ) where young sablefish reside. The trawl fishery selectivities are similar for males and females (Figure 3.28). The trawl survey selectivity curves differ between males and females, where males stay selected by the trawl survey longer (Figure 3.28). These trawl survey patterns are consistent with the idea that sablefish move out on the shelf at 2 years of age and then gradually become less available to the trawl fishery and survey as they move offshore into deeper waters.

## Fishing mortality and management path

Fishing mortality was estimated to be high in the 1970s, relatively low in the early 1980s and then increased and held relatively steady in the 1990s and 2000s (Figure 3.29). Goodman et al. (2002) suggested that stock assessment authors use a "management path" graph as a way to evaluate management and assessment performance over time. In this "management path" we plot estimated fishing mortality relative to the (current) limit value and the estimated spawning biomass relative to limit spawning biomass ( $B_{35 \%}$ ). Figure 3.30 shows that recent management has generally constrained fishing
mortality below the limit rate, and until recently kept the stock above the $B_{35 \%}$ limit. Projected 2015 and 2016 and 2017 spawning biomass is slightly below $B_{35 \%}$.

## Uncertainty

We compared a selection of parameter estimates from the Markov-Chain Monte Carlo (MCMC) simulations with the maximum-likelihood estimates, and compared each method's associated level of uncertainty (Table 3.16). Mean and median catchability estimates were nearly identical. The estimate of $F_{40 \%}$ was lower by maximum likelihood and shows some skewness as indicated by the difference between the MCMC mean and median values. MCMC standard deviations were generally slightly higher in all cases which shows that there is more uncertainty captured through MCMC.

## Retrospective analysis

Retrospective analysis is the examination of the consistency among successive estimates of the same parameters obtained as new data are added to a model. Retrospective analysis has been applied most commonly to age-structured assessments. Retrospective biases can arise for many reasons, ranging from bias in the data (e.g., catch misreporting, non-random sampling) to different types of model misspecification such as wrong values of natural mortality, or temporal trends in values set to be invariant. Classical retrospective analysis involves starting from some time period earlier in the model and successively adding data and testing if there is a consistent bias in the outputs (NRC 1998).

For this assessment, we show the retrospective trend in spawning biomass and total biomass for ten previous assessment years (2005-2014) compared to estimates from the current preferred model. This analysis is simply removing all new data that have been added for each consecutive year to the preferred model. Each year of the assessment generally adds one year of longline fishery lengths, trawl fishery lengths, longline survey lengths, longline and fishery ages (from one year prior), fishery abundance index, and longline survey index. Every other year, a trawl survey estimate and corresponding length composition are added.

In the first four years of the retrospective plot we see that estimates of spawning biomass were consistently lower for the last few years in the next assessment year (Figure 3.31a). In recent years, the retrospective plot of spawning biomass shows only small changes from year to year (e.g., Table 3.17). One common measure of the retrospective bias is Mohn's revised rho which indicates the size and direction of the bias. The revised Mohn's rho of 0.023 is very low (a small positive retrospective bias) relative to most assessments at the AFSC (Hanselman et al. 2013). The retrospective patterns are well within the posterior uncertainty of each assessment (Figure 3.31b). Recruitment estimates appear to have little trend over time with the exception of the 2002 year class which increased from a very low value to near average (Figure 3.31c). Only the 2008 year class started near average indicating low presence of 2 year olds in most of the recent data.
Examining retrospective trends can show potential biases in the model, but may not identify what their source is. Other times a retrospective trend is merely a matter of the model having too much inertia in the age-structure and other historic data to respond to the most recent data. This retrospective pattern likely to be considered mild, but at issue is the "one-way" pattern in the early part of the retrospective time series. It is difficult to isolate the cause of this pattern but several possibilities exist. For example, hypotheses could include environmental changes in catchability, time-varying natural mortality, or changes in selectivity of the fishery or survey. One other issue is that fishery abundance and lengths, and all age compositions are added into the assessment with a one year lag to the current assessment. This estimate of rho is down from 0.089 in 2013 and about the same as in 2014 ( 0.019 ), which we attribute to two factors: 1) 2003 was dropped out of the retrospective window which had a relatively large change from the terminal year; and 2) The updated catch data that was used in 2014 added a significant amount of catch in the early part of the retrospective window, which increased the estimate of spawning biomass at the
recent low point. We will monitor and explore these patterns in the future.
The 2010 Joint Plan Team requested that we examine what the current model configuration would have recommended for ABCs going back in time to see how much model and author changes has affected management advice. We examined this in the 2011 SAFE and concluded that despite many model changes, including growth updates and a split-gender model, the management advice would have been similar (Hanselman et al. 2011).

## Harvest Recommendations

## Reference fishing mortality rate

Sablefish are managed under Tier 3 of NPFMC harvest rules. Reference points are calculated using recruitments from 1977-2012. The updated point estimates of $B_{40 \%}, F_{40 \%}$ and $F_{35 \%}$ from this assessment are $102,807 \mathrm{t}$ (combined across the EBS, AI, and GOA), 0.094 , and 0.112 , respectively. Projected female spawning biomass (combined areas) for 2016 is $86,471 \mathrm{t}\left(84 \%\right.$ of $\left.B_{40 \%}\right)$, placing sablefish in sub-tier "b" of Tier 3. The maximum permissible value of $F_{A B C}$ under Tier 3 b is 0.078 , which translates into a 2016 ABC (combined areas) of $11,795 \mathrm{t}$. The OFL fishing mortality rate is 0.093 which translates into a 2016 OFL (combined areas) of $13,397 \mathrm{t}$. If the stock were in Tier 3a (above the $B_{40 \%}$ reference point), the 2016 ABC would be $14,164 \mathrm{t}$. Model projections indicate that this stock is not subject to overfishing, overfished, nor approaching an overfished condition.

## Population projections

A standard set of projections is required for each stock managed under Tiers 1, 2, or 3 of Amendment 56. This set of projections encompasses seven harvest scenarios designed to satisfy the requirements of Amendment 56, the National Environmental Policy Act, and the Magnuson-Stevens Fishery Conservation and Management Act (MSFCMA).

For each scenario, the projections begin with the vector of 2015 numbers at age as estimated in the assessment. This vector is then projected forward to the beginning of 2016 using the schedules of natural mortality and selectivity described in the assessment and the best available estimate of total (year-end) catch for 2015. In each subsequent year, the fishing mortality rate is prescribed on the basis of the spawning biomass in that year and the respective harvest scenario. In each year, recruitment is drawn from an inverse Gaussian distribution whose parameters consist of maximum likelihood estimates determined from recruitments estimated in the assessment. Spawning biomass is computed in each year based on the time of peak spawning and the maturity and weight schedules described in the assessment. Total catch after 2015 is assumed to equal the catch associated with the respective harvest scenario in all years. This projection scheme is run 1,000 times to obtain distributions of possible future stock sizes, fishing mortality rates, and catches.
Five of the seven standard scenarios will be used in an Environmental Assessment prepared in conjunction with the final SAFE. These five scenarios, which are designed to provide a range of harvest alternatives that are likely to bracket the final TAC for 2016, are as follow ("max $F_{A B C}$ " refers to the maximum permissible value of $F_{A B C}$ under Amendment 56):

Scenario 1: In all future years, $F$ is set equal to $\max F_{A B C}$. (Rationale: Historically, TAC has been constrained by ABC , so this scenario provides a likely upper limit on future TACs.)

Scenario 2: In 2016 and 2017, $F$ is set equal to a constant fraction of $\max F_{A B C}$, where this fraction is equal to the ratio of the realized catches in 2012-2014 to the TAC for each of those years. For the remainder of the future years, maximum permissible ABC is used. (Rationale: In many fisheries the ABC is routinely not fully utilized, so assuming an average ratio of F will yield more realistic projections.)
Scenario 3: In all future years, $F$ is set equal to $50 \%$ of $\max F_{A B C}$. (Rationale: This scenario
provides a likely lower bound on $F_{A B C}$ that still allows future harvest rates to be adjusted downward when stocks fall below reference levels.)

Scenario 4: In all future years, $F$ is set equal to the 2010-2014 average $F$. (Rationale: For some stocks, TAC can be well below ABC, and recent average $F$ may provide a better indicator of $F_{T A C}$ than $F_{A B C}$.)

Scenario 5: In all future years, $F$ is set equal to zero. (Rationale: In extreme cases, TAC may be set at a level close to zero.)

Two other scenarios are needed to satisfy the MSFCMA's requirement to determine whether a stock is currently in an overfished condition or is approaching an overfished condition. These two scenarios are as follows (for Tier 3 stocks, the MSY level is defined as $B_{35 \%}$ ):

Scenario 6: In all future years, $F$ is set equal to $F_{O F L}$. (Rationale: This scenario determines whether a stock is overfished. If the stock is expected to be 1) above its MSY level in 2015 or 2) above $1 / 2$ of its MSY level in 2015 and above its MSY level in 2025 under this scenario, then the stock is not overfished.)
Scenario 7: In 2016 and 2017, $F$ is set equal to $\max F_{A B C}$, and in all subsequent years $F$ is set equal to $F_{O F L}$. (Rationale: This scenario determines whether a stock is approaching an overfished condition. If the stock is 1 ) above its MSY level in 2017 or 2 ) above $1 / 2$ of its MSY level in 2017 and expected to be above its MSY level in 2027 under this scenario, then the stock is not approaching an overfished condition.)

Spawning biomass, fishing mortality, and yield are tabulated for the seven standard projection scenarios (Table 3.18). The difference for this assessment for projections is in Scenario 2 (Author's F); we use pre-specified catches to increase accuracy of short-term projections in fisheries (such as sablefish) where the catch is usually less than the ABC. This was suggested to help management with setting more accurate preliminary ABCs and OFLs for 2016 and 2017. The methodology for determining these pre-specified catches is described below in Specified catch estimation.

## Status determination

In addition to the seven standard harvest scenarios, Amendments 48/48 to the BSAI and GOA Groundfish Fishery Management Plans require projections of the likely OFL two years into the future. While Scenario 6 gives the best estimate of OFL for 2016, it does not provide the best estimate of OFL for 2017, because the mean 2016 catch under Scenario 6 is predicated on the 2016 catch being equal to the 2016 OFL, whereas the actual 2016 catch will likely be less than the 2016 OFL. A better approach is to estimate catches that are more likely to occur as described below under Specified Catch Estimation. The executive summary contains the appropriate one- and two-year ahead projections for both ABC and OFL.
Under the MSFCMA, the Secretary of Commerce is required to report on the status of each U.S. fishery with respect to overfishing. This report involves the answers to three questions: 1) Is the stock being subjected to overfishing? 2) Is the stock currently overfished? 3) Is the stock approaching an overfished condition?

Is the stock being subjected to overfishing? The official catch estimate for the most recent complete year (2014) is $11,582 \mathrm{t}$. This is less than the 2014 OFL of $16,160 \mathrm{t}$. Therefore, the stock is not being subjected to overfishing.

Harvest Scenarios \#6 and \#7 (Table 3.18) are intended to permit determination of the status of a stock with respect to its minimum stock size threshold (MSST). Any stock that is below its MSST is defined to be overfished. Any stock that is expected to fall below its MSST in the next two years is defined to be
approaching an overfished condition. Harvest Scenarios \#6 and \#7 are used in these determinations as follows:
Is the stock currently overfished? This depends on the stock's estimated spawning biomass in 2015:
a. If spawning biomass for 2015 is estimated to be below $1 / 2 B 35 \%$, the stock is below its MSST.
b. If spawning biomass for 2015 is estimated to be above $B 35 \%$, the stock is above its MSST.
c. If spawning biomass for 2015 is estimated to be above $1 / 2 B_{35} \%$ but below $B 35 \%$, the stock's status relative to MSST is determined by referring to harvest Scenario \#6 (Table 3.18). If the mean spawning biomass for 2025 is below $B 35 \%$, the stock is below its MSST. Otherwise, the stock is above its MSST.
Is the stock approaching an overfished condition? This is determined by referring to harvest Scenario \#7 (Table 3.18):
a. If the mean spawning biomass for 2017 is below $1 / 2 B 35 \%$, the stock is approaching an overfished condition.
b. If the mean spawning biomass for 2017 is above $B_{35 \%}$, the stock is not approaching an overfished condition.
c. If the mean spawning biomass for 2017 is above $1 / 2 B_{35 \%}$ but below $B 35 \%$, the determination depends on the mean spawning biomass for 2027. If the mean spawning biomass for 2027 is below $B 35 \%$, the stock is approaching an overfished condition. Otherwise, the stock is not approaching an overfished condition.
Based on the above criteria and the results of the seven scenarios in Table 3.18, the stock is not overfished and is not approaching an overfished condition.

## Specified catch estimation

In response to GOA Plan Team minutes in 2010, we have established a consistent methodology for estimating current-year and future year catches in order to provide more accurate two-year projections of ABC and OFL to management. We explained the methods and gave examples in the 2011 SAFE (Hanselman et al. 2011). Going forward, for current year catch, we are applying an expansion factor to the official catch on or near October 1 by the 3-year average of catch taken between October 1 and December 31 in the last three complete catch years (e.g. 2012-2014 for this year).

For catch projections into the next two years, we are using the ratio of the last three official catches to the last three TACs multiplied against the future two years' ABCs (if TAC is normally the same as ABC). This method results in slightly higher ABCs in each of the future two years of the projection, based on both the lower catch in the first year out, and on the amount of catch taken before spawning in the projection two years out.

## Bayesian analysis

The model estimates of projected spawning biomass fall near the center of the posterior distribution of spawning biomass. Most of the probability lies between 80,000 and $100,000 \mathrm{t}$ (Figure 3.32). The probability changes smoothly and exhibits a relatively normal distribution. The posterior distribution clearly indicates the stock is below $B_{40 \%}$.
Scatter plots of selected pairs of model parameters were produced to evaluate the shape of the posterior distribution (Figure 3.33). The plots indicate that the parameters are reasonably well defined by the data. As expected, catchabilities, $F_{40 \%}$, and ending spawning biomass were confounded. The catchability of the longline survey is most confounded with ending spawning biomass because it has the most influence in the model in recent abundance predictions.

We estimated the posterior probability that projected abundance will fall, or stay below thresholds of $17.5 \%$ (MSST), and $35 \%$ (MSY), and $40 \%$ ( $B_{\text {target }}$ ) of the unfished spawning biomass based on the posterior probability estimates. Abundance was projected for 14 years. For management, it is important to know the risk of falling under these thresholds. The probability that spawning biomass falls below key biological reference points was estimated based on the posterior probability distribution for spawning biomass. The probability that next year's spawning biomass was below $B_{35 \%}$ was 0.89 . During the next three years, the probability of being below $\mathrm{B}_{17.5 \%}$ is near zero, the probability of being below $\mathrm{B}_{35 \%}$ is 0.98 , and the probability of staying below $\mathrm{B}_{40 \%}$ is near $100 \%$ (Figure 3.34).

## Alternative Projection

We also use an alternative projection that considers uncertainty from the whole model by running projections within the model. This projection propagates uncertainty throughout the entire assessment procedure and is based on $10,000,000$ MCMC (burnt-in and thinned) using the standard Tier 3 harvest rules. The projection shows wide credible intervals on future spawning biomass (Figure 3.35). The $B_{35 \%}$ and $B_{40 \%}$ reference points are based on the 1979-2013 recruitments, and this projection predicts that the mean and median spawning biomass will stay below $B_{35 \%}$ until after 2020, and then return to $B_{40 \%}$ if average recruitment is attained. This projection is run with the same ratio for catch as described in Alternative 2 above, except for all future years instead of the next two.

## Acceptable biological catch

We recommend a 2016 ABC of $\mathbf{1 1 , 7 9 5} \mathbf{t}$. The maximum permissible ABC for 2016 based on Tier 3b of the harvest control rule, uses an adjusted $F_{40 \%}$ which yields $11,795 \mathrm{t}$. The maximum permissible ABC for 2016 is $14 \%$ lower than the 2015 ABC of $13,657 \mathrm{t}$. The 2014 assessment projected a $10 \%$ decrease in ABC for 2016 from 2015. This slightly larger decrease is supported by a new low in the domestic longline survey index time series that offset the small increases in the fishery abundance index seen in 2014 and the Gulf of Alaska trawl survey index in 2015. The fishery abundance index has been trending down since 2007. The 2014 IPHC GOA sablefish index was not used in the model, but was similar and trending low in 2013 and 2014. The 2008 year class showed potential to be large in previous assessments based on patterns in the age and length compositions. However the estimate in this year's assessment is only just above average because the recent large overall decrease in the longline survey and trawl indices have lowered the overall scale of the population. Spawning biomass is projected to decline through 2018, and then is expected to increase assuming average recruitment is achieved in the future. ABCs are projected to decrease in 2017 to $10,782 \mathrm{t}$ and 10,869 t in 2018 (see Table 3.18).

## Area allocation of harvests

The combined ABC has been apportioned to regions using weighted moving average methods since 1993; these methods reduce the magnitude of inter-annual changes in the apportionment. Weighted moving average methods are robust to uncertainties about movement rates and measurement error of the biomass distribution, while adapting to current information about the biomass distribution. The 1993 TAC was apportioned using a 5 year running average with emphasis doubled for the current year survey abundance index in weight (relative population weight or RPW). Since 1995, the ABC was apportioned using an exponential weighting of regional RPWs. Exponential weighting is implied under certain conditions by the Kalman filter. The exponential factor is the measurement error variance divided by the prediction error variance (Meinhold and Singpurwalla 1983). Prediction error variance depends on the variances of the previous year's estimate, the process error, and the measurement error. When the ratio of measurement error variance to process error variance is $r$, the exponential factor is equal to
$1-2 /(\sqrt{4 r+1}+1)$ (Thompson 2004). For sablefish we do not estimate these values, but instead set the
exponential factor at $1 / 2$, so that, except for the first year, the weight of each year's value is $1 / 2$ the weight of the following year. The weights are year index $5: 0.0625 ; 4: 0.0625 ; 3: 0.1250 ; 2: 0.2500 ; 1: 0.5000$. A $(1 / 2)^{x}$ weighting scheme, where $x$ is the year index, reduced annual fluctuations in regional ABC, while keeping regional fishing rates from exceeding overfishing levels in a stochastic migratory model ( J . Heifetz, 1999, NOAA, pers. comm.). Because mixing rates for sablefish are sufficiently high and fishing rates sufficiently low, moderate variations of biomass-based apportionment would not significantly change overall sablefish yield unless there are strong differences in recruitment, growth, and survival by area (Heifetz et al. 1997).
Previously, the Council approved apportionments of the ABC based on survey data alone. Starting with the 2000 ABC , the Council approved an apportionment based on survey and fishery data. The fishery and survey information were combined to apportion ABC using the following method: The RPWs based on the fishery data were weighted with the same exponential weights used to weight the survey data (year index $5: 0.0625 ; 4: 0.0625 ; 3: 0.1250 ; 2: 0.2500 ; 1: 0.5000)$. The fishery and survey data were combined by computing a weighted average of the survey and fishery estimates, with the weight inversely proportional to the variability of each data source. The variance for the fishery data has typically been twice that of the survey data, so the survey data was weighted twice as much as the fishery data. Below are area-specific apportionments following the traditional apportionment scheme, which we are not
recommending for 2016:

| Apportionments are <br> based on survey and <br> fishery information | $\mathbf{2 0 1 4}$ <br> ABC <br> Percent | Survey <br> RPW | Fishery <br> RPW | $\mathbf{2 0 1 5}$ <br> ABC <br> Percent | $\mathbf{2 0 1 5}$ | ABC | $\mathbf{2 0 1 6}$ |
| :--- | :---: | :---: | :---: | :---: | ---: | ---: | :--- |
| Total |  |  |  |  | 13,657 | $\mathbf{1 1 , 7 9 5}$ | Change |
| Bering Sea | $10 \%$ | $15 \%$ | $16 \%$ | $10 \%$ | 1,333 | $\mathbf{1 , 8 1 6}$ | $36 \%$ |
| Aleutians | $13 \%$ | $13 \%$ | $15 \%$ | $13 \%$ | 1,802 | $\mathbf{1 , 6 2 7}$ | $-10 \%$ |
| Gulf of Alaska | $77 \%$ | $72 \%$ | $69 \%$ | $77 \%$ | 10,522 | $\mathbf{8 , 3 5 2}$ | $-21 \%$ |
| Western | $14 \%$ | $14 \%$ | $13 \%$ | $14 \%$ | 1,473 | $\mathbf{1 , 1 3 6}$ | $-23 \%$ |
| Central | $44 \%$ | $43 \%$ | $36 \%$ | $44 \%$ | 4,658 | $\mathbf{3 , 4 5 1}$ | $-26 \%$ |
| W. Yakutat* | $15 \%$ | $16 \%$ | $17 \%$ | $15 \%$ | 1,567 | $\mathbf{1 , 3 7 4}$ | $-12 \%$ |
| E. Yakutat / Southeast* | $27 \%$ | $27 \%$ | $34 \%$ | $27 \%$ | 2,823 | $\mathbf{2 , 3 9 1}$ | $-15 \%$ |

Following the standard apportionment scheme, we have observed that the objective to reduce variability in apportionment was not being achieved. Since 2007, the mean change in apportionment by area has increased annually (Figure 3.36A). While some of these changes may actually reflect interannual changes in regional abundance, they most likely reflect the high movement rates of the population and the high variability of our estimates of abundance in the Bering Sea and Aleutian Islands. For example, the apportionment for the Bering Sea has varied drastically since 2007, attributable to high variability in both survey abundance and fishery CPUE estimates in the Bering Sea (Figure 3.36B). These large annual changes in apportionment result in increased variability of ABCs by area, including areas other than the Bering Sea (Figure 3.36C). Because of the high variability in apportionment seen in recent years, we do not believe the standard method is meeting the goal of reducing the magnitude of interannual changes in the apportionment. Because of these reasons, we recommended fixing the apportionment at the proportions from the 2013 assessment, until the apportionment scheme is thoroughly reevaluated and reviewed. A Ph.D. student with the University of Alaska-Fairbanks began a project in 2013 with the objectives of re-examining the apportionment strategy and conducting a management strategy evaluation. A spatial sablefish model has been developed, but the management strategy evaluation is in early stages of development. Meanwhile, it seems imprudent to move to an interim apportionment or return to the former scheme until more satisfactory methods have been identified and evaluated. Therefore, for 2016, we recommend continuing with the apportionment fixed at the proportions used in 2015.

|  |  | Standard <br> apportionment <br> for $2016 ~ A B C$ | Recommended fixed <br> apportionment <br> for 2016 ABC | Difference <br> from 2015 |
| :--- | :---: | :---: | :---: | :---: |
| Area | $\mathbf{2 0 1 5 ~ A B C}$ | 11,795 | $\mathbf{1 1 , 7 9 5}$ | $-13.6 \%$ |
| Total | 13,657 | 1,816 | $\mathbf{1 , 1 5 1}$ | $-13.6 \%$ |
| Bering Sea | 1,333 | 1,627 | $\mathbf{1 , 5 5 7}$ | $-13.6 \%$ |
| Aleutians | 1,802 | 8,352 | $\mathbf{9 , 0 8 7}$ | $-13.6 \%$ |
| Gulf of Alaska (subtotal) | 10,522 | 1,136 | $\mathbf{1 , 2 7 2}$ | $-13.6 \%$ |
| Western | 1,473 | 3,451 | $\mathbf{4 , 0 2 3}$ | $-13.6 \%$ |
| Central | 4,658 | 1,374 | $\mathbf{1 , 3 5 3}$ | $-13.6 \%$ |
| W. Yakutat** | 1,567 | 2,391 | $\mathbf{2 , 4 3 8}$ | $-13.6 \%$ |
| E. Yak. / Southeast* | 2,823 |  |  |  |

${ }^{*}$ Fixed at the 2013 assessment apportionment proportions (Hanselman et al. 2012). ${ }^{* *}$ Before 95:5 hook and line: trawl split shown below.

| Adjusted for 95:5 hook- | $\frac{\text { Year }}{}$ | W. Yakutat | E. Yakutat/Southeast |
| :--- | :---: | :---: | :---: |
| and-line: trawl split in | 2016 | $1,475 \mathrm{t}$ | $2,316 \mathrm{t}$ |
| EGOA | 2017 | $1,348 \mathrm{t}$ | $2,118 \mathrm{t}$ |

## Overfishing level (OFL)

Applying an adjusted $F_{35 \%}$ as prescribed for OFL in Tier 3b, results in a value of 13,397 t for the combined stock. The OFL is apportioned by region, Bering Sea (1,304 t), AI (1,766 t), and GOA (10,326 t ), by the same method as the ABC apportionment.

## Ecosystem considerations

Ecosystem considerations for the Alaska sablefish fishery are summarized in Table 3.19.

## Ecosystem effects on the stock

## Prey population trends

Young-of-the-year sablefish prey mostly on euphausiids (Sigler et al. 2001) and copepods (Grover and Olla 1990), while juvenile and adult sablefish are opportunistic feeders. Larval sablefish abundance has been linked to copepod abundance and young-of-the-year abundance may be similarly affected by euphausiid abundance because of their apparent dependence on a single species (McFarlane and Beamish 1992). The dependence of larval and young-of-the-year sablefish on a single prey species may be the cause of the observed wide variation in annual sablefish recruitment. No time series is available for copepod and euphausiid abundance, so predictions of sablefish abundance based on this predator-prey relationship are not possible.

Juvenile and adult sablefish feed opportunistically, so diets differ throughout their range. In general, sablefish $<60 \mathrm{~cm}$ consume more euphausiids, shrimp, and cephalopods, while sablefish $>60 \mathrm{~cm}$ consume more fish (Yang and Nelson 2000). In the GOA, fish constituted $3 / 4$ of the stomach content weight of adult sablefish with the remainder being invertebrates (Yang and Nelson 2000). Of the fish found in the diets of adult sablefish, pollock were the most abundant item while eulachon, capelin, Pacific herring, Pacific cod, Pacific sand lance, and flatfish also were found. Squid were the most important invertebrate and euphausiids and jellyfish were also present. In southeast Alaska, juvenile sablefish also consume juvenile salmon at least during the summer months (Sturdevant et al. 2009). Off the coast of Oregon and California, fish made up 76 percent of the diet (Laidig et al. 1997), while euphausiids dominated the diet off the southwest coast of Vancouver Island (Tanasichuk 1997). Off Vancouver Island, herring and other fish were increasingly important as sablefish size increased; however, the most important prey item was euphausiids. It is unlikely that juvenile and adult sablefish are affected by availability and abundance of
individual prey species because they are opportunistic feeders. The only likely way prey could affect growth or survival of juvenile and adult sablefish is by overall changes in ecosystem productivity.
Predators/Competitors: The main juvenile sablefish predators are adult coho and chinook salmon, which prey on young-of-the-year sablefish during their pelagic stage. Sablefish were the fourth most commonly reported prey species in the salmon troll logbook program from 1977 to 1984 (Wing 1985), however the effect of salmon predation on sablefish survival is unknown. The only other fish species reported to prey on sablefish in the GOA is Pacific halibut; however, sablefish comprised less than $1 \%$ of their stomach contents (M. Yang, October 14, 1999, NOAA, pers. comm.). Although juvenile sablefish may not be a prominent prey item because of their relatively low and sporadic abundance compared to other prey items, they share residence on the continental shelf with potential predators such as arrowtooth flounder, halibut, Pacific cod, bigmouth sculpin, big skate, and Bering skate, which are the main piscivorous groundfishes in the GOA (Yang et al. 2006). It seems possible that predation of sablefish by other fish is significant to the success of sablefish recruitment even though they are not a common prey item.

Sperm whales are likely a major predator of adult sablefish. Fish are an important part of sperm whale diet in some parts of the world, including the northeastern Pacific Ocean (Kawakami 1980). Fish have appeared in the diets of sperm whales in the eastern AI and GOA. Although fish species were not identified in sperm whale diets in Alaska, sablefish were found in $8.3 \%$ of sperm whale stomachs off of California (Kawakami 1980).

Sablefish distribution is typically thought to be on the upper continental slope in deeper waters than most groundfish. However, during the first two to three years of their life sablefish inhabit the continental shelf. Length samples from the NMFS bottom trawl survey suggest that the geographic range of juvenile sablefish on the shelf varies dramatically from year to year. In particular, juveniles utilize the Bering Sea shelf extensively in some years, while not at all in others (Shotwell et al. 2014). Juvenile sablefish ( $<60$ cm FL) prey items overlap with the diet of small arrowtooth flounder. On the continental shelf of the GOA, both species consumed euphausiids and shrimp predominantly; these prey are prominent in the diet of many other groundfish species as well. This diet overlap may cause competition for resources between small sablefish and other groundfish species.
Changes in the physical environment: Mass water movements and temperature changes appear related to recruitment success. Above-average recruitment was somewhat more likely with northerly winter currents and much less likely for years when the drift was southerly. Recruitment was above average in $61 \%$ of the years when temperature was above average, but was above average in only $25 \%$ of the years when temperature was below average. Growth rate of young-of-the-year sablefish is higher in years when recruitment is above average (Sigler et al. 2001). Shotwell et al. (2014) showed that colder than average wintertime sea surface temperatures in the central North Pacific may represent oceanic conditions that create positive recruitment events for sablefish in their early life history.
Anthropogenic changes in the physical environment: The Essential Fish Habitat Environmental Impact Statement (EFH EIS) (NMFS 2005) concluded that the effects of commercial fishing on the habitat of sablefish is minimal or temporary in the current fishery management regime primarily based on the criterion that sablefish are currently above Minimum Stock Size Threshold (MSST).
Juvenile sablefish are partly dependent on benthic prey ( $18 \%$ of diet by weight) and the availability of benthic prey may be adversely affected by fishing. Little is known about effects of fishing on benthic habitat or the habitat requirements for growth to maturity. Although sablefish do not appear to be directly dependent on physical structure, reduction of living structure is predicted in much of the area where juvenile sablefish reside and this may indirectly reduce juvenile survivorship by reducing prey availability or by altering the abilities of competing species to feed and avoid predation.

## Fishery effects on the ecosystem

Fishery-specific contribution to bycatch of prohibited species, forage species, HAPC biota, marine mammals and birds, and other sensitive non-target species: The sablefish fishery catches significant portions of the shark and thornyhead rockfish total catch (Table 3.4). The sablefish fishery catches the majority of grenadier total catch; the annual amount is variable (Table 3.5). The trend in seabird catch is variable, but is substantially low compared to the 1990s, presumably due to widespread use of measures to reduce seabird catch. Prohibited species catches (PSC) in the targeted sablefish fisheries are dominated by halibut ( 334 t /year) and golden king crab ( 47,000 individuals/year). Halibut catches were average in 2015, while golden king crab catches have dropped precipitously from almost 200,000 individuals in 2011 to $3,193 \mathrm{t}$ in 2014 and 11,270 t in 2015 (Table 3.6).

The shift from an open-access to an IFQ fishery has increased catching efficiency which has reduced the number of hooks deployed (Sigler and Lunsford 2001). Although the effects of longline gear on bottom habitat are poorly known, the reduced number of hooks deployed during the IFQ fishery must reduce the effects on benthic habitat. The IFQ fishery likely has also reduced discards of other species because of the slower pace of the fishery and the incentive to maximize value from the catch.
Fishery-specific concentration of target catch in space and time relative to predator needs in space and time (if known) and relative to spawning components: The sablefish fishery largely is dispersed in space and time. The longline fishery lasts $8-1 / 2$ months. The quota is apportioned among six regions of Alaska.

Fishery-specific effects on amount of large size target fish: The longline fishery catches mostly medium and large-size fish which are typically mature. Length frequencies from the pot fishery in the BSAI are very similar to the longline fishery. The trawl fishery, which on average accounts for about $10 \%$ of the total catch, often catches slightly smaller fish. The trawl fishery typically occurs on the continental shelf where juvenile sablefish sometimes occur. Catching these fish as juveniles reduces the yield available from each recruit.

Fishery-specific contribution to discards and offal production: Discards of sablefish in the longline fishery are small, typically less than $5 \%$ of total catch (Table 3.3). The catch of sablefish in the longline fishery typically consists of a high proportion of sablefish, $90 \%$ or more. However, at times grenadiers may be a significant catch and they are almost always discarded.

Fishery-specific effects on age-at-maturity and fecundity of the target species: The shift from an openaccess to an IFQ fishery has decreased harvest of immature fish and improved the chance that individual fish will reproduce at least once (Sigler and Lunsford 2001).
Fishery-specific effects on EFH non-living substrate: The primary fishery for sablefish is with longline gear. While it is possible that longlines could move small boulders it is unlikely fishing would persist where this would often occur. Relative to trawl gear, a significant effect of longlines on bedrock, cobbles, or sand is unlikely.

## Data gaps and research priorities

There is little information on early life history of sablefish and recruitment processes. A better understanding of juvenile distribution, habitat utilization, and species interactions would improve understanding of the processes that determine the productivity of the stock. Better estimation of recruitment and year class strength would improve assessment and management of the sablefish population.
The Essential Fish Habitat 5-year Update will begin in 2016 and new habitat suitability models will be distributed on all life history stages for FMP species where data were available. Following evaluation of this information for sablefish, we plan to include the new EFH model results and maps in future assessments. A newly revamped species-specific ecosystem consideration (SEC) protocol is also planned
to be introduced over the next several years. The SECs will likely replace the Ecosystem Consideration section of the single-species assessment reports and include updated species profiles, climate vulnerability analyses, and stock/habitat prioritization information. The intention of these SECs is to improve the process of integrating ecosystem information into the stock assessments and facilitate ecosystem based fishery management.

Future sablefish research is going to focus on several directions:

1) Evaluating different apportionment strategies for the ABC .
2) Refine survey abundance index model for inclusion in future assessment model that accounts for whale depredation and potentially includes gully abundance data and other covariates.
3) Refine fishery abundance index to utilize a core fleet, and identify covariates that affect catch rates.
4) Improve knowledge of sperm whale and killer whale depredation in the fishery and begin to quantify depredation effects on fishery catch rates.
5) Continue to explore the use of environmental data to aid in determining recruitment.
6) An integrated GOA Ecosystem project funded by the North Pacific Research Board is underway and is looking at recruitment processes of major groundfish including sablefish. We hope to work closely with this project to help understand sablefish recruitment dynamics.
7) Develop a species-specific report card and enhanced ecosystem considerations section based on the the results of the GOA project described above.
8) We are developing a spatially explicit research assessment model that includes movement, which will help in examining smaller-scale population dynamics while retaining a single stock hypothesis Alaska-wide sablefish model. This is to include a management strategy evaluation of apportionment strategies.

## Tables

Table 3.1. Alaska sablefish catch ( t ). The values include landed catch and discard estimates. Discards were estimated for U.S. fisheries before 1993 by multiplying reported catch by $2.9 \%$ for fixed gear and $26.9 \%$ for trawl gear (1994-1997 averages) because discard estimates were unavailable. Eastern includes West Yakutat and East Yakutat / Southeast. 2015 catches are as of 10/29/2015 (www.akfin.org).

| Year | Grand total | Bering Sea | Aleutians | Western | BY AREA |  | West Yakutat | $\begin{gathered} \text { East } \\ \text { Yak/SEO } \end{gathered}$ | Unknown | BY GEAR |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  |  | Central | Eastern |  |  |  | Fixed | Trawl |

Table 3.7. Summary of management measures with time series of catch, ABC, OFL, and TAC.

| Year | $\operatorname{Catch}(t)$ | OFL | $\mathbf{A B C}$ | TAC | Management measure |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 1980 | 10,444 |  |  | 18,000 | Amendment 8 to the Gulf of Alaska Fishery Management Plan established the West and East Yakutat management areas for sablefish. |
| 1981 | 12,604 |  |  | 19,349 |  |
| 1982 | 12,048 |  |  | 17,300 |  |
| 1983 | 11,715 |  |  | 14,480 |  |
| 1984 | 14,109 |  |  | 14,820 |  |
| 1985 | 14,465 |  |  | 13,480 | Amendment 14 of the GOA FMP allocated sablefish quota by gear type: $80 \%$ to fixed gear and $20 \%$ to trawl gear in WGOA and CGOA and $95 \%$ fixed to $5 \%$ trawl in the EGOA. |
| 1986 | 28,892 |  |  | 21,450 | Pot fishing banned in Eastern GOA. |
| 1987 | 35,163 |  |  | 27,700 | Pot fishing banned in Central GOA. |
| 1988 | 38,406 |  |  | 36,400 |  |
| 1989 | 34,829 |  |  | 32,200 | Pot fishing banned in Western GOA. |
| 1990 | 32,115 |  |  | 33,200 | Amendment 15 of the BSAI FMP allocated sablefish quota by gear type: $50 \%$ to fixed gear in and $50 \%$ to trawl in the EBS, and $75 \%$ fixed to $25 \%$ trawl in the Aleutian Islands. |
| 1991 | 27,073 |  |  | 28,800 |  |
| 1992 | 24,932 |  |  | 25,200 | Pot fishing banned in Bering Sea (57 FR 37906). |
| 1993 | 25,417 |  |  | 25,000 |  |
| 1994 | 23,577 |  |  | 28,840 |  |
| 1995 | 20,692 |  |  | 25,300 | Amendment 20 to the Gulf of Alaska Fishery Management Plan and 15 to the Bering Sea/Aleutian Islands Fishery Management Plan established IFQ management for sablefish beginning in 1995. These amendments also allocated $20 \%$ of the fixed gear allocation of sablefish to a CDQ reserve for the Bering Sea and Aleutian Islands. |
| 1996 | 17,275 |  |  | 19,380 | Pot fishing ban repealed in Bering Sea except from June 1- $30 .$ |
| 1997 | 14,607 | 27,900 | 19,600 | 17,200 | Maximum retainable allowances for sablefish were revised in the Gulf of Alaska. The percentage depends on the basis species. |
| 1998 | 13,867 | 26,500 | 16,800 | 16,800 |  |
| 1999 | 13,585 | 24,700 | 15,900 | 15,900 |  |
| 2000 | 15,565 | 21,400 | 17,300 | 17,300 |  |
| 2001 | 14,064 | 20,700 | 16,900 | 16,900 |  |
| 2002 | 14,748 | 26,100 | 17,300 | 17,300 |  |
| 2003 | 16,411 | 28,900 | 18,400 | 20,900 |  |
| 2004 | 17,518 | 30,800 | 23,000 | 23,000 |  |
| 2005 | 16,580 | 25,400 | 21,000 | 21,000 |  |
| 2006 | 15,551 | 25,300 | 21,000 | 21,000 |  |
| 2007 | 15,957 | 23,750 | 20,100 | 20,100 |  |
| 2008 | 14,674 | 21,310 | 18,030 | 18,030 | Pot fishing ban repealed in Bering Sea for June 1-30 (74 FR 28733). |
| 2009 | 13,128 | 19,000 | 16,080 | 16,080 |  |
| 2010 | 11,980 | 21,400 | 15,230 | 15,230 |  |
| 2011 | 12,971 | 20,700 | 16,040 | 16,040 |  |
| 2012 | 13,868 | 20,400 | 17,240 | 17,240 |  |
| 2013 | 13,642 | 19,180 | 16,230 | 16,230 |  |
| 2014 | 11,582 | 16,160 | 13,722 | 13,722 |  |
| 2015 | 10,094 | 16,128 | 13,657 | 13,657 |  |

Table 3.8. Sample sizes for aged fish and length data collected from Alaska sablefish. Japanese fishery data from Sasaki (1985), U.S. fishery data from the observer databases, and longline survey data from longline survey databases. Trawl survey data from AKFIN. All fish were sexed before measurement, except for the Japanese fishery data.

|  | LENGTH |  |  |  |  |  | AGE |  |  |

Table 3.10. Sablefish abundance index values (1,000's) for Alaska (200-1,000 m) including deep gully habitat, from the Japan-U.S. Cooperative Longline Survey, Domestic Longline Survey, and Japanese and U.S. longline fisheries. Relative population number equals CPUE in numbers weighted by respective strata areas. Relative population weight equals CPUE measured in weight multiplied by strata areas. Indices were extrapolated for survey areas not sampled every year, including Aleutian Islands 1979, 1995, 1997, 1999, 2001, 2003, 2005, and 2007, 2009, 2011, 2013, and 2015, and Bering Sea 1979-1981, 1995, 1996, 1998, 2000, 2002, 2004, 2006, 2008, 2009, 2010, 2012, and 2014. NMFS trawl survey biomass estimates (kilotons) are from the Gulf of Alaska at depths $<500 \mathrm{~m}$.

Table 3.11. Count of stations where sperm (S) or killer whale (K) depredation occurred in the six sablefish management areas. The number of stations sampled that are used for RPN calculations are in parentheses. Areas not surveyed in a given year are left blank. If there were no whale depredation data taken, it is denoted with an " $\mathrm{n} / \mathrm{a}$ ". Killer whale depredation did not always occur on all skates of gear, and only those skates with depredation were cut from calculations of RPNs and RPWs.

[^2]Table 3.19. Analysis of ecosystem considerations for the sablefish fishery.

| Indicator | Observation | Interpretation | Evaluation |
| :---: | :---: | :---: | :---: |
| ECOSYSTEM EFFECTS ON STOCK |  |  |  |
| Prey availability or abundance trends |  |  |  |
| Zooplankton | None | None | Unknown |
| Predator population trends |  |  |  |
| Changes in habitat quality |  |  |  |
| Temperature regime | Warm increases recruitment | Variable recruitment | No concern (can't affect) |
| Prevailing currents | Northerly increases recruitment | Variable recruitment | No concern (can't affect) |
| FISHERY EFFECTS ON ECOSYSTEM |  |  |  |
| Fishery contribution to bycatch |  |  |  |
| Prohibited species | Small catches | Minor contribution to mortality | No concern |
| Forage species | Small catches | Minor contribution to mortality | No concern |
| HAPC biota (seapens/whips, corals, sponges, anemones) | Small catches, except long-term reductions predicted | Long-term reductions predicted in hard corals and living structure | Possible concern |
| Marine mammals and birds | Bird catch about 10\% total | Appears to be decreasing | Possible concern |
| Sensitive non-target species | Grenadier, spiny dogfish, and unidentified shark catch notable | Grenadier catch high but stable, recent shark catch is small | Possible concern for grenadiers |
| Fishery concentration in space and time | IFQ less concentrated | IFQ improves | No concern |
| Fishery effects on amount of large size target fish | IFQ reduces catch of immature | IFQ improves | No concern |
| Fishery contribution to discards and offal production | sablefish $<5 \%$ in longline fishery, but $30 \%$ in trawl fishery | IFQ improves, but notable discards in trawl fishery | Trawl fishery discards definite concern |
| Fishery effects on age-atmaturity and fecundity | trawl fishery catches smaller fish, but only small part of total catch | slightly decreases | No concern |

## Figures

## Appendix 3A.--Sablefish longline survey - fishery interactions

NMFS has requested the assistance of the fishing fleet to avoid the annual sablefish longline survey since the inception of sablefish IFQ management in 1995. We requested that fishermen stay at least five nautical miles away from each survey station for 7 days before and 3 days after the planned sampling date (3 days allow for survey delays). Beginning in 1998, we also revised the longline survey schedule to avoid the July 1 rockfish trawl fishery opening as well as other short, but less intense fisheries.

## History of interactions

Publicity, the revised longline survey schedule, and fishermen cooperation generally have been effective at reducing fishery interactions. Distribution of the survey schedule to all IFQ permit holders, radio announcements from the survey vessel, and the threat of a regulatory rolling closure have had intermittent success at reducing the annual number of longline fishery interactions.
Since 2000, the number of vessels fishing near survey stations has remained relatively low. During the past several surveys, many fishing vessels were contacted by the survey vessel and in most cases fishermen were aware of the survey or willing to help out by fishing other grounds to avoid potential survey interactions.

Longline Survey-Fishery Interactions

|  |  | Longline |  | Trawl |  | Pot |  | Total |  |

## Recommendation

We have followed several practical measures to alleviate fishery interactions with the survey. Trawl fishery interactions generally have decreased; longline fishery interactions have been low but continue to occur. Discussions with vessels encountered on the survey indicated an increasing level of "hired" skippers who are unaware of the survey schedule. Publicizing the survey schedule to skippers who aren't
quota shareholders should be improved. We will continue to work with association representatives and individual fishermen from the longline and trawl fleets to reduce fishery interactions and ensure accurate estimates of sablefish abundance.

## Appendix 3B.-Supplemental catch data

In order to comply with the Annual Catch Limit (ACL) requirements, two new datasets have been generated to help estimate total catch and removals from NMFS stocks in Alaska.

The first dataset, non-commercial removals, estimates total removals that do not occur during directed groundfish fishing activities. This includes removals incurred during research, subsistence, personal use, recreational, and exempted fishing permit activities, but does not include removals taken in fisheries other than those managed under the groundfish FMP. These estimates represent additional sources of removals to the existing Catch Accounting System estimates. For sablefish, these estimates can be compared to the research removals reported in previous assessments (Hanselman et al. 2010) (Table 3B.1). The sablefish research removals are substantial relative to the fishery catch and compared to the research removals for many other species. These research removals support a dedicated longline survey. Additional sources of significant removals are bottom trawl surveys and the International Pacific Halibut Commissions longline survey. Recreational removals are relatively minor for sablefish. Total removals from activities other than directed fishery has ranged from 239-359 t in recent years. This represents $\sim 1.5-2.5$ percent of the recommended ABC annually. These removals represent a relatively low risk to the sablefish stock. When an assessment model is fit that includes these removals as part of the total catch, the result is an increase in ABC of comparable magnitude.

The second dataset, Halibut Fishery Incidental Catch Estimation (HFICE), is an estimate of the incidental catch of groundfish in the halibut IFQ fishery in Alaska, which is currently unobserved. To estimate removals in the Pacific halibut fishery, methods were developed by the HFICE working group and approved by the Gulf of Alaska and Bering Sea/Aleutian Islands Plan Teams and the Scientific and Statistical Committee of the North Pacific Fishery Management Council. A detailed description of the methods is available in Tribuzio et al. (2011).
These estimates are for total catch of groundfish species in the halibut IFQ fishery and do not distinguish between "retained" or "discarded" catch. These estimates should be considered a separate time series from the current CAS estimates of total catch. Because of potential overlaps HFICE removals should not be added to the CAS produced catch estimates. The overlap will apply when groundfish are retained or discarded during an IFQ halibut trip. IFQ halibut landings that also include landed groundfish are recorded as retained in eLandings and a discard amount for all groundfish is estimated for such landings in CAS. Discard amounts for groundfish are not currently estimated for IFQ halibut landings that do not also include landed groundfish. For example, catch information for a trip that includes both landed IFQ halibut and sablefish would contain the total amount of sablefish landed (reported in eLandings) and an estimate of discard based on at-sea observer information. Further, because a groundfish species was landed during the trip, catch accounting would also estimate discard for all groundfish species based on available observer information and following methods described in Cahalan et al. (2010). The HFICE method estimates all groundfish caught during a halibut IFQ trip and thus is an estimate of groundfish caught whether landed or discarded. This prevents simply adding the CAS total with the HFICE estimate because it would be analogous to counting both retained and discarded groundfish species twice. Further, there are situations where the HFICE estimate includes groundfish caught in State waters and this would need to be considered with respect to ACLs (e.g. Chatham Strait sablefish fisheries). Therefore, the HFICE estimates should be considered preliminary estimates for what is caught in the IFQ halibut fishery. With restructuring of the Observer Program improved estimates of groundfish catch in the halibut fishery began in 2013. More years of data are needed for an evaluation the effects of observer
restructuring on catch of sablefish in the halibut IFQ fishery..
The HFICE estimates of sablefish catch by the halibut fishery are substantial and represent approximately $10 \%$ of the annual sablefish ABC (Table 3B.2). Sablefish and halibut are often caught and landed in association with each other by the IFQ fishery. It is unknown what level of sablefish catch reported here is already accounted for as IFQ harvest in the CAS system because the HFICE estimates do not separate retained and discarded catch. If these were strictly additive removals, $10 \%$ would represent a significant amount of additional mortality and a potential risk to the stock, but how much is additive is unknown. The HFICE estimates may represent some valuable discard information for sablefish, but that level is unknown until these estimates are separated from the IFQ landings and CAS system.
