# Chapter 1b: An age-structured assessment of pollock (Theragra chalcogramma) from the Bogoslof Island Region 

James N. Ianelli, Taina Honkalehto, and Neal Williamson<br>Alaska Fisheries Science Center<br>National Marine Fisheries Service

## Executive Summary

In 1987 pollock catch peaked in the Bogoslof region (INPFC area 518) with over 370,000 tons reported. During the period from 1985 to 1991, a total of $932,996 \mathrm{t}$ of pollock were caught in this region. NMFS subsequently closed this area to directed pollock fishing (1992-2005) due in part to agreements under the Convention on the Conservation and Management of the Pollock Resources in the Central Bering Sea. Under this convention, the Bogoslof spawning aggregations are linked to the abundance of pollock found in international waters of the Aleutian Basin. As part of the monitoring program for the Convention, 17 annual Echo Integration Trawl (EIT) surveys of Bogoslof pollock abundance have been undertaken since 1988. This document presents an integrated analysis of these data through an age-structured assessment. Results from these analyses suggest that the survey data are very informative and that the current spawning stock size may be nearly 2 -fold higher than the $B_{40 \%}$ level (or about $77 \%$ of the $B_{100 \%}$ level). Estimates of natural mortality from these data are somewhat higher than previously assumed values for pollock in this region ( 0.256 compared to 0.20 ). The extent to which this stock is vulnerable to fisheries in other regions (e.g., the EBS shelf and in Russian waters) is a key question. As with pollock observed in the US, Russian, and international zones, the 1978 year class dominated the Bogoslof population; its strength is more than 10 times the average year class strength. Favorable environmental conditions are thought to play a major role in the production of year-classes of this magnitude. This high level of natural variability should be considered in management recommendations, particularly in setting realistic target stock levels.

Summary of Major Changes
Changes to the input data
In the winter of 2006 an echo-integration trawl (EIT) survey was conducted and the biomass estimate from this research was included in this assessment. The relative estimation errors as presented in the survey reports were included as part of the likelihood weighting (previously, a constant CV was assumed).

A separate catch time series was compiled which assumed that $60 \%$ of the Donut Hole catches could be attributed to the Bogoslof region stock.

## Changes in the assessment methodology

The same model as presented in 2005 was used for these analyses.
Changes in the assessment results
The age structured model estimates indicate that this stock is above the $B_{40 \%}$ level and hence could qualify for Tier 3a recommendations under Amendment 56 of the FMP. This results in maximum permissible ABC values of:

| Year | ABC | OFL |
| :---: | :---: | :---: |
| 2006 | $138,800 \mathrm{t}$ | $173,200 \mathrm{t}$ |
| 2007 | $173,000 \mathrm{t}$ | $216,300 \mathrm{t}$ |

These values are based on assuming that the Aleutian Basin catch time series is the most appropriate value and that the strong 1978 year class was anomalous (i.e., not solely from the Bogoslof Island spawning stock but also from other regions). Given the continued uncertainty about stock structure and lack of understanding on where Bogoslof pollock pre-recruits reside, it seems prudent to continue to set the ABC at levels suitable for bycatch in other fisheries.

## Response to SSC comments

In their December 1999 minutes, the SSC commented:
> "The SAFE contains an interesting [Bogoslof region] age-structured model for this stock using only data from the Bogoslof surveys. If we were willing to ignore the connection of Bogoslof pollock to the Aleutian Basin, then this model could provide a basis for determining ABC. However, we continue to believe that Bogoslof pollock are related to the Aleutian Basin stock, and therefore, ignoring data from the entire stock does not constitute use of best available information for this stock."

In their December 2005 minutes the SSC notes that the authors have not yet been able to explore the effect of Donut Hole catches in the 1980s on the stock assessment results. Therefore, the SSC agrees with the Plan Team to postpone acceptance of the model until this research is done.

Adding the reported catches from the Donut hole to the Bogoslof catches and analyzing results was attempted. Since the Central Bering Sea convention assumes that $60 \%$ of the Aleutian Basin pollock spawns in the Bogoslof region, the catches from the Donut hole were discounted by $60 \%$. This results in values of $B_{40 \%}$ that are between $77 \%$ and $130 \%$ higher depending assumptions about whether the 1978 year class is included. Using $B_{35 \%}$ as a proxy for $B_{m s y}$, the corresponding values range from 193-456 thousand $t$ of female spawning biomass. This is substantially lower than past "target" values used by the SSC of 2 million t of total biomass.

## Introduction

Alaska pollock (Theragra chalcogramma) are broadly distributed throughout the North Pacific with largest concentrations found in the Eastern Bering Sea. The Bogoslof region is noted for having distinct spawning aggregations that appear to be independent spawning in adjacent regions.

The Bogoslof management district (INPFC area 518) was established in 1992 in response to fisheries and surveys conducted during the late 1980s, which consistently found a discrete aggregation of spawning pollock in this area during the winter. The degree to which this aggregation represents a unique, selfrecruiting stock is unknown but the persistence of this aggregation suggests some spawning site fidelity that called for management. The Bogoslof region pollock has also been connected with the historical abundance of pollock found in the central Bering Sea (Donut Hole) due to concentrations of pollock successively moving toward this region prior to spawning (Smith 1981, Shuntov et al. 1993). Collectively, pollock found in the Donut Hole and in the Bogoslof region are considered a single stock, the Aleutian Basin stock. Currently, based on an agreement from a Central Bering Sea convention meeting, it is assumed that $60 \%$ of the Aleutian Basin pollock population spawns in the Bogoslof region. The actual distribution of Aleutian Basin pollock is unknown and likely varies depending on environmental conditions and the age-structure of the stock.

The Bogoslof component of the Aleutian Basin stock is one of three management stocks of pollock recognized in the BSAI region. The other stocks include pollock found in the large area of the Eastern Bering Sea shelf region and those in the Aleutian Islands near-shore region (i.e., less than 1000 m depth; Barbeaux et al. 2004). The Aleutian Islands, Eastern Bering Sea and Aleutian Basin stocks probably intermingle, but the exchange rate and magnitude are unknown. The degree to which the Bogoslof spawning component contributes to subsequent recruitment to the Aleutian Basin stock also is unknown. From an early life-history perspective, the opportunities for survival of eggs and larvae from the Bogoslof region seem smaller than for other areas (e.g., north of Unimak Island on the shelf). There is a high degree of synchronicity among strong year-classes from these three areas, which suggests either that the spawning source contributing to recruitment is shared or that conditions favorable for survival are shared.
From a biological perspective, the degree to which these management units are reasonable definitions depends on the active exchange among these stocks. If they are biologically distinct and have different levels of productivity, then management should be adjusted accordingly. Bailey et al. (1999) present a thorough review of population structure of pollock throughout the north Pacific region. They note that adjacent stocks were not genetically distinct but that differentiation between samples collected on either side of the N. Pacific was evident. There are some characteristics that distinguish Bogoslof region pollock from other areas. Growth rates appear different (based on mean-lengths at age) and pollock sampled in the Bogoslof Island survey tend to be much older. For example, the average percentage (by numbers of fish older than age 6) of age 15 and older pollock observed from the Bogoslof EIT survey since 1988 is $18 \%$; in the EBS region (from model estimates), the average from this period is only $2 \%$.
The information available for pollock in the Aleutian Basin and the Bogoslof Island area indicates that these fish may belong to the same "stock". The pollock found in winter surveys are generally older than age 4 and are considered distinct from eastern Bering Sea pollock. Although data on the age structure of Bogoslof pollock show that a majority of pollock originated from year classes that were also strong on the shelf, 1972, 1978, 1982, 1984, 1989, 1992, 1996, and 2000, there has been some indication that there are strong year classes appearing on the shelf that have not been as strong (in a relative sense) in the Bogoslof region (Ianelli et al., 2004). Strong year classes of pollock in Bogoslof may be functionally related to abundance on the shelf.

## Fishery

Prior to 1977, few pollock were caught in the Donut Hole or Bogoslof region (Low and Akada 1978). Japanese scientists first reported significant quantities of pollock in the Aleutian Basin in the mid-to-late 1970's, but large scale fisheries did not occur until the mid-1980's in the Donut Hole. By 1987 significant components of these catches were attributed to the Bogoslof Island region (Table 1b.1), although the actual locations are poorly documented. The Bogoslof fishery primarily targeted winter spawningaggregations. Since 1992, the Bogoslof management district has been closed to directed pollock fishing. During summer months, pollock distribution is diffuse and no directed pollock fishery has occurred.

In 1991, the only year with extensive observer data, the fishery timing coincided with the open seasons for the EBS and Aleutian Islands pollock fisheries (recall that the Bogoslof management district was not yet established). However, after March 23, 1991 the EBS region was closed to fishing and some effort was re-directed to the Aleutian Islands region but adjacent to the Bogoslof district. In subsequent years, seasons for the Aleutian Islands pollock fishery were managed separately. Bycatch and discard levels were relatively low from these areas when there was a directed fishery (e.g., 1991). Pollock retention levels are variable and have increased as bycatch levels from other fisheries in this area have increased (Table 1b.2).

## Data

## Fishery

We estimate the catch-at-age composition using the methods described by Kimura (1989) and modified by Dorn (1992). Age-length keys were constructed from length-stratified age data by stratum and sex, then applied to randomly sampled length frequency data. Length sample sizes are low except during 1985-1991 (Fig. 1b.1; Table 1b.3). The resultant catch-at-age compositions show the strong 1978 yearclass through the population as it grew over time. Indeed, in the one year where sufficient agedetermination samples were collected and processed (1987) the number of 9 -year olds dominated the catch (Table 1b.4).

## Echo-integration trawl (EIT) surveys

The National Marine Fisheries Service has conducted echo-integration-trawl (EIT) surveys for Aleutian Basin pollock spawning in the Bogoslof Island area annually since 1988, except that the survey was not conducted in 1990 or 2004, and in 1999, the survey was conducted by the Fisheries Agency of Japan. Survey reports have appeared in various publications (see list in Ianelli et al., 2005). The impact of strong year-classes, particularly for 1978 can be seen in the time series of survey length frequencies (Fig. 1b.2).
The timing of the survey has varied in different years but has generally occurred in late February and/or early March (Fig. 1b.3). Sample sizes for lengths, weights, and ages have been quite high (Table 1b.5).

Survey abundance declined between 1988 and 1994, was stable and variable, then dropped again to the level it has maintained since 2000 (Fig 1b.4; Table 1b.6). The 1989 year class recruited to the Bogoslof Island area and was partly responsible for the 1995 increase (Table 1b.7), but the abundance of all ages increased between 1994 and 1995. The decrease between 1995 and 1996 was followed by a continued decline in 1997, suggesting that the 1995 estimate may be high, or that conditions in that year affected the apparent abundance of pollock. The 1996 year class has appeared to some degree in the 2005 survey, while the 1999 and 2000 year classes appear to be strong. The locations of pollock concentrations seen in the 2006 survey is similar to that of recent years (Fig. 1b.5).

## Analytic approach

## Model structure

The age-structured analysis was conducted using the AMAK model (as is used for the Aleutian Islands pollock and BSAI Atka mackerel stocks). The technical aspects of this model are presented in these reports (Barbeaux et al. 2004, Lowe et al. 2004). Briefly, the model structure is developed following Fournier and Archibald's (1982) methods, with a number of similarities to Methot's extension (1990). The model is implemented using automatic differentiation software developed as a set of libraries under the C++ language (AD Model Builder). The catch-equation was formulated assuming fishing mortality occurred instantaneously at the mid-point of the year. The first age of recruitment was set at age 5 since younger fish are rarely found in the survey or the fishery. Fish of age 15 and older were pooled into a single age group (labeled 15+).

## Parameters estimated independently

## Natural Mortality and maturity at age

Wespestad and Terry (1984), estimated natural mortality to be about 0.2 . Here, this assumption was relaxed and estimated within the model. Maturity at age was assumed to be (Ianelli et al. 2004):

| Age | $\mathbf{5}$ | $\mathbf{6}$ | $\mathbf{7}$ | $\mathbf{8}$ | $\mathbf{9}$ | $\mathbf{1 0}$ | $\mathbf{1 1}$ | $\mathbf{1 2}$ | $\mathbf{1 3}$ | $\mathbf{1 4}$ | $\mathbf{1 5 +}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Prop. Mature | 0.842 | 0.902 | 0.948 | 0.964 | 0.970 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 |

## Length and Weight at Age

EIT survey estimates of mean body-weight at age by year, sexes combined (Table 1b.8) were used to convert model estimates of catch-at-age (in numbers) to model estimates of total annual harvests (by weight). The mean body weight values were computed by dividing the EIT estimated biomass-at-age by the estimated population numbers-at-age. The 2004 data were computed as averages from the 2005 and 2003 average weights at age.

## EIT survey catchability

For the models presented here, survey catchability was assumed to equal 1.0-implying that the survey represents an absolute abundance index.

## Parameters estimated conditionally

In total, 61 parameters were estimated. These include vectors describing recruitment variability in the first year (as ages 5-15 in 1977) and the recruitment deviations (at age 5) from 1977-2006. Additionally, projected recruitment variability was also estimated (using the estimated variance of past recruitments) for 10 years (2006-2015). The two-parameter stock-recruitment curve is included in addition to a term that allows the average recruitment before 1977 (that comprises the initial age composition in that year) to have a mean value different from subsequent years. With the value for recruitment variability about the curve, the total for recruitment-related parameters is 53.
Fishing mortality is parameterized to be the same for all ages greater than age 6 since this fishery comprises mainly spawning aggregations and only one year of fishery age composition data is available. As with the survey data, the ages 5 and 6 occur less commonly in this area and hence the vulnerability for these ages is estimated (resulting in 6 parameters, 3 each for the survey and fishery). As noted above, natural mortality is estimated as a free parameter.

The likelihood components can thus be partitioned into the following groups:

- Log-normal indices of abundance for the EIT survey (values of $\sigma=0.2$ were assumed)
- Fishery and survey proportions-at-age estimates (multinomial with effective sample sizes presented in Table 1b.9).
- Slight selectivity constraints on ages 5 and 6 for both the survey and fishery, constant value for ages 7 and older
- Stock-recruitment: non-informative prior distribution assumed to fit the stochastic stockrecruitment relationship within the integrated model

## Model evaluation

In 2005 seven alternative models were evaluated. These examined assumptions about stock-recruitment productivity, natural mortality, survey catchability, and the extent of the survey index area. Rather than completely repeat those analyses here, a single model where the stock-recruitment parameters and natural mortality were estimated and survey catchability was assumed to equal 1.0 was used. From initial model runs, this latter assumption proved important since with the added Donut Hole catch, the population levels tended towards unreasonably high levels (when survey catchability was estimated, it went to very small values). For evaluation purposes, the impact of adding in historic Donut-hole catches to the Bogoslof region catches was considered. As shown below, two alternative assumptions about projections are also considered since they have large implications on biomass reference points and maximum permissible ABC levels.

## Results

The main model results are summarized in Table 1b.10. Natural mortality was similar to last year's estimate but slightly higher for model 1 and slightly lower for model 2 . The impact of the 2006 survey information was small relative to last year's assessment but the effect of adding the Aleutian Basin catches was quite high, more than doubling the estimated peak biomass levels (Fig. 1b.6). While the fits for Model 2 (including the Aleutian Basin catches) were somewhat worse than for Model 1, it was adopted since assigning the Aleutian Basin catches to the Bogoslof region seems most relevant given current stock-structure hypotheses.
The estimated selectivity patterns are similar for both the survey and fishery (Fig. 1b.7), which is unsurprising because the timing and location of the fishery and the EIT survey largely overlap.
The overall trend in abundance relative to the EIT survey time series shows a series of positive residuals during the late 1980s and early 1990s (Fig. 1b.8). The fit to the EIT survey age composition data shows some variability in the estimates of above-average year-classes (Fig. 1b.9). The proportions-at-age observed in the survey are generally consistent with what appeared in the fishery from 1987 (Fig. 1b.10).
Estimated numbers-at-age are presented in Table 1b. 11 and estimated catch-at-age presented in Table 1b.12. Estimated summary biomass (age $5+$ ), female spawning biomass, age 5 recruitment, and fullselection fishing mortality for Model 2 is given in Table 1b.13. A comparison of these biomass levels, together with the predicted and observed survey estimates, is given in Figure 1b.11.

## Abundance and exploitation trends

The abundance and exploitation pattern estimated from Model 2 shows that the fishing mortality rate was high during the late 1980s when the largest removals reported from this region occurred (Fig. 1b.12). Biomass levels increased from 1979 to the mid-1980's (Fig. 1b.13; Table 1b.13) primarily due to the recruitment of the strong 1978 year class (Table 1b.11). Compared to last year's assessment, the peak stock size this year is estimated to be substantively higher, while the recent stock levels are very similar (Table 1b.14).

## Recruitment

As with pollock observed in the US, Russian, and international zones, the 1978 year class dominated the Bogoslof population as a major event. For the Bogoslof region the magnitude of this year-class is more than 10 times the average (Fig. 1b.14). Favorable environmental conditions are thought to play a major role in the production of year-classes of this magnitude. For the Bogoslof region, density dependent processes affecting subsequent recruitment likely occur outside of this region since the area is relatively small and the winter spawning aggregations appear to disperse or move to other regions. Since this and issues related to stock structure remain uncertain, harvest recommendations based on a fitted stockrecruitment relationships were avoided (Fig. 1b.15).

## Projections and harvest alternatives

## Amendment 56 Reference Points

Amendment 56 to the BSAI Groundfish Fishery Management Plan (FMP) defines "overfishing level" (OFL), the fishing mortality rate used to set OFL ( $F_{O F L}$ ), the maximum permissible ABC, and the fishing mortality rate used to set the maximum permissible ABC. The fishing mortality rate used to set ABC ( $F_{A B C}$ ) may be less than this maximum permissible level, but not greater. Reference points related to maximum sustainable yield (MSY) were estimated but considered inappropriate. Therefore, reference points for pollock in the Bogoslof region are based solely on Tier 3 of Amendment 56. The reference point estimates varied widely depending on the model and the inclusion of the 1978 year class (Table 1b.15; Fig. 1b.16). Since such a large part of the removals from the Aleutian Basin consisted of the 1978 year class, and that this year-class is the largest on record for the EBS shelf region, it seems that assuming all of the production arose from the Bogoslof spawning stock (or at least 60\% of it) is too high.
Therefore, the 1978 year class as estimated in the present model is treated as an anomalous event and not included for projection purposes. The reference points (excluding the 1978 year class estimate) are thus:

$$
\begin{aligned}
& B_{100 \%}=551,825 \text { thousand } \mathrm{t} \text { female spawning biomass } \\
& B_{40 \%}=220,730 \text { thousand } \mathrm{t} \text { female spawning biomass } \\
& B_{35 \%}=193,139 \text { thousand } \mathrm{t} \text { female spawning biomass. }
\end{aligned}
$$

## Standard Harvest Scenarios and Projection Methodology

A standard set of projections is required for each stock managed under Tiers 1, 2, or 3, of Amendment 56. This set of projections encompasses seven harvest scenarios designed to satisfy the requirements of Amendment 56, the National Environmental Policy Act, and the Magnuson-Stevens Fishery Conservation and Management Act (MSFCMA).

For each scenario, the projections begin with the vector of 2006 numbers at age estimated in the assessment. This vector is then projected forward to the beginning of 2006 using the schedules of natural mortality and selectivity described in the assessment and the best available estimate of total (year-end) catch for 2006. In each subsequent year, the fishing mortality rate is prescribed on the basis of the spawning biomass in that year and the respective harvest scenario. In each year, recruitment is drawn from an inverse Gaussian distribution whose parameters consist of maximum likelihood estimates determined from recruitments estimated in the assessment. Spawning biomass is computed in each year based on the time of peak spawning and the maturity and weight schedules described in the assessment. Total catch is assumed to equal the catch associated with the respective harvest scenario in all years. This projection scheme is run 1000 times to obtain distributions of possible future stock sizes, fishing mortality rates, and catches.

Five of the seven standard scenarios will be used in an Environmental Assessment prepared in conjunction with the final SAFE. These five scenarios, which are designed to provide a range of harvest
alternatives that are likely to bracket the final TAC for 2007, are as follow (" $m a x F_{A B C}$ " refers to the maximum permissible value of $F_{A B C}$ under Amendment 56):

Scenario 1: In all future years, $F$ is set equal to $\max F_{A B C}$. (Rationale: Historically, TAC has been constrained by ABC, so this scenario provides a likely upper limit on future TACs.)
Scenario 2: In all future years, $F$ is set equal to a constant fraction of $\max F_{A B C}$, where this fraction is equal to the ratio of the $F_{A B C}$ value for 2006 recommended in the assessment to the max $F_{A B C}$ for 2007. (Rationale: When $F_{A B C}$ is set at a value below $\max F_{A B C}$, it is often set at the value recommended in the stock assessment.) The results from this scenario were omitted since they are the same as Scenario 1.
Scenario 3: In all future years, $F$ is set equal to the 2002-2006 average $F$. (Rationale: For some stocks, TAC can be well below ABC, and recent average $F$ may provide a better indicator of $F_{T A C}$ than $F_{A B C}$.)
Scenario 4: In all future years, $F$ is set equal to F75\%. (Rationale: This scenario was requested from public comment on the DSEIS proposed in 2006. )
Scenario 5: In all future years, $F$ is set equal to zero. (Rationale: In extreme cases, TAC may be set at a level close to zero.)

Two other scenarios are needed to satisfy the MSFCMA's requirement to determine whether a stock is currently in an overfished condition or is approaching an overfished condition. These two scenarios are (for Tier 3 stocks, the MSY level is defined as $B_{35 \%}$ ):
Scenario 6: In all future years, F is set equal to $F_{\text {OFL }}$. (Rationale: This scenario determines whether a stock is overfished. If the stock is expected to be 1) above its MSY level in 2006 or 2) above $1 / 2$ of its MSY level in 2006 and above its MSY level in 2017 under this scenario, then the stock is not overfished.)
Scenario 7: In 2007 and 2008, $F$ is set equal to $\max F_{A B C}$, and in all subsequent years, $F$ is set equal to $F_{O F L}$. (Rationale: This scenario determines whether a stock is approaching an overfished condition. If the stock is expected to be above its MSY level in 2018 under this scenario, then the stock is not approaching an overfished condition.)

## Projections and status determination

For the purposes of these projections, we present results based on selecting the $F_{40 \%}$ harvest rate as the max $F_{A B C}$ value and use $F_{35 \%}$ as a proxy for $F_{m s y}$. Scenarios 1 through 7 were projected 14 years from 2006 (Table 1b.16). Under Scenario 1, the expected spawning biomass is projected to increase to above the $B_{40 \%}$ by the year 2007. Under this scenario, the yields are expected to vary between $50-200$ thousand tons. If the highly conservative catch levels (estimated from the last 5 years) are to continue, then the stock is projected to increase.

Any stock that is below its minimum stock size threshold (MSST) is defined to be overfished. Any stock that is expected to fall below its MSST in the next two years is defined to be approaching an overfished condition. Harvest scenarios 6 and 7 are used in these determinations as follows:
Is the stock overfished? This depends on the stock's estimated spawning biomass in 2007:
a) If spawning biomass for 2007 is estimated to be below $1 / 2 B_{35 \%}$ the stock is below its MSST.
b) If spawning biomass for 2007 is estimated to be above $B_{35 \%}$, the stock is above its MSST.
c) If spawning biomass for 2007 is estimated to be above $1 / 2 B_{35 \%}$ but below $B_{35 \%}$, the stock's status relative to MSST is determined by referring to harvest scenario 6 (Table 16). If the mean spawning biomass for 2018 is below $B_{35 \%}$, the stock is below its MSST. Otherwise, the stock is above its MSST.

Is the stock approaching an overfished condition? This is determined by referring to harvest Scenario 7:
a) If the mean spawning biomass for 2009 is below $1 / 2 B_{35 \%}$, the stock is approaching an overfished condition.
b) If the mean spawning biomass for 2009 is above $B_{35 \%}$, the stock is not approaching an overfished condition.
c) If the mean spawning biomass for 2009 is above $1 / 2 B_{35 \%}$ but below $B_{35 \%}$, the determination depends on the mean spawning biomass for 2018. If the mean spawning biomass for 2018 is below $B_{35 \%}$, the stock is approaching an overfished condition. Otherwise, the stock is not approaching an overfished condition.

For scenarios 6 and 7, we conclude that pollock is not below MSST for the year 2007, nor is it expected to be approaching an overfished condition based on Scenario 7.

## Specification of OFL and Maximum Permissible ABC

In this section standard age-structured results are presented for a Tier 3a (amendment 56) ABC calculation. Past methods and a recommendation are presented in the subsequent section. For Model 2, the year 2006 female spawning biomass is estimated to be 198,446 thousand tons (at the time of spawning, assuming the stock is fished at F40\%). This is slightly below the $B_{40 \%}$ value of 220,730 but above the $B_{35 \%}$ value of 193,139 . The maximum-permissible ABC and OFL levels are thus $138,800 t$ and $173,200 \mathrm{t}$, respectively. The values for 2008 (assuming 2007 catches are similar to 2006) gives ABC and OFL of $173,000 \mathrm{t}$ and $216,300 \mathrm{t}$, respectively

## ABC Recommendation

Since 1999 the North Pacific Fishery Management Council (NPFMC) has generally been presented with a number of alternative methods for computing ABC values for the Bogoslof region. These have included:

1. Using a biomass-adjusted harvest rate rule (with 2,000,000 ton estimate as a target stock size) with an estimate of a $F_{A B C}$ based on growth, natural mortality, and maturation rate.
2. Using a harvest rate as a simple fraction of natural mortality rate (e.g., $F_{A B C}=0.75 M$ ).
3. An approach using the age-structured model presented in this document.

Historically, the NPFMC Science and Statistical Committee (SSC) considered the third approach using the age-structured model to be inappropriate since it was thought this region only covered part of the stock. While this may still be the case, the analysis carried out here is intended to provide some contrast and provides a more complete evaluation of the data from this region.

The approach 1) and 2) above are provided below for comparison (along with alternative assumptions about $F_{A B C}$ level for 1). Using method 1) above and given the 2006 survey estimate of exploitable biomass of 0.253 million $t$ and $M=0.2$ and considering of a target stock size of 2 million tons, the $F_{A B C}$ level is computed as:

$$
F_{a b c} \leq F_{40 \%} \bullet\left(\frac{B_{2006}}{B_{\text {Target }}}-0.05\right) /(1-0.05)
$$

Assuming that $F_{40 \%}=0.27$ (as in past assessments), this gives a fishing mortality rate of 0.0217 that translates to an exploitation rate of 0.0215 . This value multiplied by the most recent survey estimate ( $240,000 \mathrm{t}$ ), gives a 2007 ABC of $5,218 \mathbf{t}$ for the Bogoslof region. The value assumed for $F_{40 \%}$ that is critical for this calculation was based on uncertain assumptions about selectivity, natural mortality, growth, and maturation. Some of these assumptions were reevaluated here using a simple knife-edged selectivity at age 4 and age 5 . Female pollock were specified to be $50 \%$ mature by age 5 and immature for younger pollock and $100 \%$ mature for older pollock with a natural morality of 0.3 . This results in an $F_{40 \%}$ level of 0.22 for the age- 4 knife edge assumption and $F_{40 \%}=0.33$ for the age- 5 knife-edge
assumption. These two scenarios provide ABCs for 2007 that would be $4,252 \mathrm{t}$ or $6,378 \mathrm{t}$ for the age- 4 and age- 5 knife edge assumptions, respectively. Clearly, these rules are sensitive to assumptions about expected selectivity, assumed growth, natural mortality, and maturation rates.
The approach for computing ABC levels under 2 ) above (a Tier 5 computation) simply uses the most recent survey biomass estimate applied to an adjusted natural mortality. Given a value of $M=0.3$ then the ABC level would be (2006 survey biomass $\times M \times 0.75$ ) of $54,000 \mathrm{t}$ at a biomass of $240,000 \mathrm{t}$. With $M=$ 0.2 , the ABC would be $36,000 \mathrm{t}$.

The age-structured model presented here provides a number of new results. First, the value estimated for $F_{40 \%}$ (assuming the selectivity and natural mortality are as estimated and given the assumed proportion mature at age) is higher than that assumed above (although the exploitation rate-catch over total biomass-is about 30\%). Also, the reference points are quite different. Assuming that the 2,000,000 t "target" represents $\sim 1$ million $t$ of female spawning biomass, then the target of 220,730 t of female spawning biomass presented above is substantially smaller. The current Bogoslof stock size is about nearly two times the target level ( $B_{40 \%}$ ) and about $77 \%$ of the "unfished" level (which given observed recruitment at age 5 to this region is $551,825 \mathrm{t}$ of female spawning biomass). The maximum-permissible ABC using the age-structured model gives a 2007 ABC level of 138,800 t.

In summary, there is a broad range of ABC levels that have been calculated under the NPFMC guidelines. The third approach (age-structured model) results in the highest ABC levels. The age-structured model, while currently under review by the SSC, could be argued to represent an alternative method to set ABCs and subsequent TACs. Given the current uncertainty about stock structure and our lack of understanding on where Bogoslof pollock pre-recruits reside, it seems prudent to set the ABC at levels suitable for bycatch in other fisheries. This would be closest to the recent 5-year average fishing mortality level (Scenario 4) which indicates an ABC level of 471 t . A summary of the results is given in Table 1b.17.

## Ecosystem considerations

In general, a number of key issues for ecosystem conservation and management can be highlighted. These include:

- Preventing overfishing;
- Avoiding habitat degradation;
- Minimizing incidental bycatch (via multi-species analyses of technical interactions);
- Controlling the level of discards; and
- Considering multi-species trophic interactions relative to harvest policies.

For the case of pollock, the NPFMC and NMFS continue to manage the fishery on the basis of these issues in addition to the single-species harvest approach. The prevention of overfishing is clearly set out as a main guideline for management. Habitat degradation has been minimized in the pollock fishery by converting the industry to pelagic-gear only. Bycatch in the pollock fleet is closely monitored by the NMFS observer program, and individual species caught incidentally are managed on that basis. Discarding rates have been greatly reduced in this fishery and multi-species interactions is an ongoing research project within NMFS with extensive food-habit studies and simulation analyses to evaluate a number of "what if" scenarios with multi-species interactions.

As reported in Loughlin and Miller (1989) pups of Northern fur seals, Callorhinus ursinus, were first observed on Bogoslof Island in 1980. By 1988 the population had grown at a rate of $57 \% / \mathrm{yr}$ to over 400 individuals, including $80+$ pups, 159 adult females, 22 territorial males, and 188 subadult males. They noted that rookery is in the same location where solitary male fur seals were seen in 1976 and 1979 and is adjacent to a large northern sea lion rookery. On July 22, 2005 NMFS survey efforts counted 1,123 adult males, a substantial increase over this time period (L. Fritz, AFSC, pers. comm.). This suggests that conditions in the ecosystem have changed and appear to favor Northern fur seals. The extent that this is
due to environmental conditions is unknown. However, pollock abundance may play only a small role since during peak abundance levels, the Northern fur seal abundance was at very low levels. Also, pollock are most concentrated in this region during winter months when Northern fur seals have migrated to more southern areas.

Table 1b.7. Biomass (tons) of pollock as surveyed in the Bogoslof region, 1988-2006. Note that in 1999 the Fishery Agency of Japan conducted the survey. These estimates are based on the biomass from the entire vicinity surveyed in each year rather than the specified "convention area" (see Ianelli et al. (2005) for a list of references documenting these surveys).
"Relative Error" is the coefficient of variation assumed in fitting the model. Note that for 1988, 1989, and 1999 values were unavailable, hence they were set to the maximum value found from the other years. Source: McKelvey et al. 2006.

| Year | Survey biomass <br> estimates (t) | Survey area <br> (nmi2) | Relative <br> error |  |  |
| ---: | ---: | ---: | ---: | :---: | :---: |

Table 1b.8. Annual average pollock weights-at-age (kg) used for the Bogoslof region assessment model. These values are used in the model for computing the predicted fishery catch (in weight) and for computing biomass levels for Bogoslof pollock. The italicized values used for 1977-1990 are the average from 1991-1995 whereas the values in 1999 and 2004 are averages from the year before and the year after. The weight at age in 2006 is the average from 2003-2005.

Table 1b.10. Results comparing fits for Models 1 and 2 with the analogous model from the 2005 assessment. Note that the relative error from McKelvey et al. (2006) was used in the current assessment. In 2005, a CV=0.20 was assumed for all survey years (hence, likelihood values for the survey index are not comparable).

## Figures

Figure 1b.1. Length frequency proportions of Bogoslof pollock based on observer data from fishery catches for 1978-2004. Note that sample sizes for most years (except 1985-1991) are very small.

Figure 1b.2. Pollock proportion-at-length estimates from the 1988-2006 Bogoslof Area (INPFC area 518) EIT surveys. There were no surveys in 1990 and in 2004.

Figure 1b.3. Time periods of Bogoslof EIT surveys as conducted by AFSC (except in 1999 when the survey was conducted by the Japan Fishery Agency). Cruise names are listed at the beginning of each survey period.

Figure 1b.4. Pollock biomass estimates from the 1988-2006 Bogoslof Area (INPFC area 518) EIT surveys in thousands of tons. There were no surveys in 1990 and in 2004.

Figure 1b.5. Pollock biomass in metric tons (t) (vertical lines) and trawl hauls (circles) along tracklines from the winter 2006 echo integration-trawl survey of walleye pollock in the Bogoslof Island area. The Central Bering Sea Convention area is indicated by a dashdotted line (from McKelvey et al. 2006).

Figure 1b.6. Comparisons of different model specifications on estimates of age 5 and older Bogoslof region pollock biomass (tons). See text for explanation of different model assumptions.

Figure 1b.7. Selectivity patterns estimated (and assumed for ages 7 and older) for the Bogoslof pollock survey and fishery under Model 2.

Figure 1b.8. Predicted Model 2 EIT survey biomass (line) versus observed survey estimates (circles) biomass (tons) of Bogoslof region pollock, 1988-2006. Vertical bars represent two times the annual standard deviations assumed for fitting the survey abundance index.

Figure 1b.9. Model 2 estimates (lines) versus observed EIT survey (bars) proportions-at-age of Bogoslof region pollock, 1988-2005.

Figure 1b.10. Model 2 estimates (lines) versus observed fishery (bars) proportions-at-age of Bogoslof region pollock, 1987 (the only year where age-data are available).

Figure 1b.11. Bogoslof pollock biomass measures as estimated for Model 2, 1977-2006. Units are in tons. The thick line represents the model prediction of the survey biomass. Note that 50:50 sex ratio is assumed for estimates of female spawning biomass.

Figure 1b.12. Estimated Model 2 historical fishing mortality rates (age 5-15) for Bogoslof pollock, 1977-2005. The horizontal line represents the estimate of $F_{40 \%}$.

Figure 1b.13. Total age $5+$ Model 2 Bogoslof pollock biomass estimated by the model with $\underline{+2}$ standard deviations of the estimates (dashed lines).

Figure 1b.14. Age-5 recruitment with $\pm 2$ standard deviations of the estimates for Bogoslof region pollock.

Figure 1b.15. Bogoslof pollock age-5 recruitment vs female spawning biomass 1977-2006. The curve represents the estimated stock-recruitment relationship.

Figure 1b.16. Bogoslof pollock projected catch at ABC for the two models (Model 1 with Bogoslof catches only, Model 2 with Aleutian Basin catches included) and under different assumptions about the included recruitment time series-the "b" option includes the 1978 year class in the biological reference points and in the simulations whereas the others are based on recruitments from 1979-2006 only.
